**Abstract.** In recent years, there has been much focus on developing core cryptographic primitives based on lattice assumptions, driven by the NIST call for postquantum key encapsulation and digital signature algorithms. However, more work must be conducted on efficient privacy-preserving protocols based on quantum-safe assumptions.

Electronic voting is one such privacy-preserving protocol whose adoption is increasing across the democratic world. E-voting offers both a fast and convenient alternative to postal voting whilst further ensuring cryptographic privacy of votes and offering full verifiability of the process. Owing to the sensitivity of voting and its infrastructure challenges, it is crucial to ensure security against quantum computers is baked into e-voting solutions.

We present an e-voting scheme from quantum-safe assumptions based on the hardness of the RLWE and NTRU lattice problems, providing concrete parameters and an efficient implementation. Our design achieves a factor 5*.*3× reduction in ciphertext size,  $2.5\times$  reduction in total communication cost, and  $2\times$  reduction in total computation time compared to the state-of-the-art lattice-based voting scheme by Aranha et al. (ACM CCS 2023). We argue that the efficiency of this scheme makes it suitable for real-world elections.

Our scheme makes use of non-ternary NTRU secrets to achieve optimal parameters. In order to compute the security of our design, we extend the ternary-NTRU work of Ducas and van Woerden (ASIACRYPT 2021) by determining the concrete fatigue point (for general secrets) of NTRU to be  $q = 0.0058 \cdot \sigma^2 \cdot d^{2.484}$  (above which parameters become *overstretched*) for modulus *q*, ring dimension *d*, and secrets drawn from a Gaussian of parameter  $\sigma$ . We consider this relation to be of independent interest and demonstrate its significance by improving the efficiency of the (partially) blind signature scheme by del Pino and Katsumata (CRYPTO 2022).

**Keywords:** Lattice Cryptography · Electronic Voting · NTRU

### **1 Introduction**

With the advent of quantum computers, all public key primitives based on the hardness of factoring or computing discrete logarithms will be deemed insecure.

To mitigate this, there has been an international effort to replace these primitives with ones based on assumptions conjectured to be secure against quantum adversaries. This process, led by the National Institute of Standards and Technology (NIST) in the US, has recently concluded with the selection of standards for post-quantum key encapsulation

This is the same version as our paper published at IACR CiC Volume 1 Issue 4 [\[HSS25\]](#page-34-0).

<span id="page-0-0"></span><sup>a</sup>Work done in part while visiting the Norwegian University of Science and Technology.

and digital signature algorithms. Three of four standards  $[SAB+22, LDK+22, PFH+22]$  $[SAB+22, LDK+22, PFH+22]$ are built from *structured lattice assumptions*; Ring Short Integer Solution (RSIS) [\[Ajt96,](#page-31-0) [PR06,](#page-36-1) [LM06\]](#page-35-1), Ring Learning With Errors (RLWE) [\[Reg05,](#page-37-1) [LPR10\]](#page-36-2), and NTRU [\[HPS98\]](#page-34-1), or the *module* versions of the two former assumptions (MSIS/MLWE) [\[LS15\]](#page-36-3). Despite this standardization effort, there is still much work to be done in designing *privacypreserving* primitives from quantum-safe assumptions. In this work, we focus on one of these; electronic voting (e-voting). More precisely, we consider internet voting which allows for fully remote ballot casting via a voter's device as opposed to voting machines at a polling station, though our framework could in theory be implemented in this setting also. Herein, 'e-voting' should be read as synonymous with internet voting.

**Electronic Voting.** E-voting has become increasingly prevalent with the first experiments for democratic elections beginning around the turn of the millennium. The first binding election to be carried out online was for the Arizona primary in 2000 [\[CBS00\]](#page-33-0). In 2005, Estonia offered internet voting nationally [\[Vin15\]](#page-38-0) and in 2023, over 63% of the votes cast in Estonian parliamentary elections were cast online<sup>[1](#page-1-0)</sup>. Switzerland used its Swiss Post voting system in the 2023 national elections for the first time [\[Swi23\]](#page-37-2) and continues to be one of the leaders in e-voting uptake. Ontario, Canada increasingly offers online voting with 177 municipalities exclusively using online voting in the 2018 municipal elections [\[CAE19\]](#page-33-1). In Australia, over 650,000 online voters participated in the 2021 state election in New South Wales [\[New21\]](#page-36-4). E-voting is also used in the cryptographic community, where the International Association for Cryptologic Research (IACR) is using Helios [\[Adi08\]](#page-31-1) for their elections<sup>[2](#page-1-1)</sup>.

E-voting has a number of attractive advantages. Analysis of Estonian local elections in 2017 showed the per-vote cost of online ballots was a factor  $2\times$  to  $10\times$  cheaper than election-day paper ballots  $[KCK<sup>+</sup>18]$  $[KCK<sup>+</sup>18]$ . Moreover, the 2023 Estonian parliamentary elections revealed that the environmental impact (CO2 emissions) of paper ballots was 180 times higher than that for online ballots and its adoption has resulted in a high voter satisfaction and turnout rate [\[Sol01,](#page-37-3) [SMPS16\]](#page-37-4).

E-voting offers to enhance both the *integrity* and *privacy* of voting. The first attractive property is verifiability; both individual and universal. Individual verifiability allows a voter to check that their ballot was recorded correctly in the final count, whilst universal verifiability allows anyone to check that parties involved in ballot processing carried out their tasks correctly. While this represents a great bolstering to the integrity of the voting process, it can be executed whilst preserving the privacy of voters and their ballots. The second significant property enabled by e-voting is the distribution of the ballot processing. A distributed decryption ensures privacy of ballots since a single honest decryption server prevents a connection between voters and ballots.

Moreover, we emphasise the importance of *long-term* privacy of electronically cast ballots, where encrypted ballots submitted today potentially can be tied to users in the future if we can break the encryption scheme. The increasing deployment of e-voting protocols currently outpaces solutions providing security against quantum computers. Evidenced by the rapid adoption of the PQC NIST standards, the urgency to defend against a potential quantum adversary is plain to see. One possible solution for e-voting is to deploy schemes providing *everlasting privacy* [\[HMMP23\]](#page-34-2), however, these schemes do not offer integrity against quantum computers, creating problems down the road whenever quantum computers are available. It is not certain that the public will be the first to know when classical assumptions are breakable, and it is thus essential that quantum security be baked into the designs for e-voting from the outset, and particularly to construct e-voting schemes based on assumptions conjectured to be secure against quantum adversaries.

<span id="page-1-0"></span><sup>1</sup>[valimised.ee/en/archive/statistics-about-internet-voting-estonia](https://www.valimised.ee/en/archive/statistics-about-internet-voting-estonia)

<span id="page-1-1"></span><sup>2</sup> [iacr.org/elections/eVoting](https://www.iacr.org/elections/eVoting)

From a desire to achieve these privacy enhancements has emerged the 'mix-and-decrypt' paradigm. Here, multiple servers verifiably shuffle encrypted ballots before they are decrypted in a distributed manner. This is commonly achieved by combining a verifiable mix-net [\[Cha81\]](#page-33-2) with a distributed public-key encryption scheme. Many previous voting designs have used this structure and in 2019, Switzerland (via its national postal service Swiss Post), deployed a national e-voting infrastructure using this paradigm and the Bayer-Groth mix-net [\[BG12\]](#page-32-0).

**Voting from Quantum-Safe Assumptions.** Despite much success in developing evoting protocols, only a few are based on assumptions believed to be quantum-safe. The most notable works are the schemes by del Pino et al. [ $dPLNS17$ ], Aranha et al. [ $ABG+21$ ], Farzaliyev et al. [\[FWK21\]](#page-34-4), and Aranha et al. [\[ABGS23\]](#page-31-3), the latter being the most efficient scheme based on (Ring) SIS and (Ring) LWE. Of these schemes, only the last one satisfies the golden mix-and-decrypt standard for general ballots. Even then, the communication cost of this scheme is around two orders of magnitude greater than the one employed by Swiss Post based on classical assumptions.

The inefficiency of the state-of-the-art scheme in [\[ABGS23\]](#page-31-3) stems from the need to decrypt ballots correctly being hindered by a few key features of their design.

- 1. In order to optimise the computational cost of lattice-based protocols and to rely on reductions to worst-case problems, one would like to use polynomial rings whose dimension is a power of two. This imposes the first constraint on parameters ([\[ABGS23\]](#page-31-3) uses ring dimension 4096).
- 2. The mixing and distributed decryption stages both use homomorphic operations on encrypted ballots. This has the effect of increasing the noise within each ciphertext. To accommodate this, one must use a ring with a larger modulus to 'soak up' this extra noise. This larger modulus itself increases the size of objects in the scheme and decreases the security of the underlying assumption, in turn requiring a larger ring dimension to ensure that the concrete instantiation is still secure.
- 3. The distributed decryption process requires decryption servers to use so-called 'noise-drowning' [\[BD10\]](#page-32-1) to ensure that decryption shares do not leak anything about the server's decryption key. Further, each decryption server must prove, in zero-knowledge, that they have applied this noise drowning operation. So far, proving knowledge of such a large element over lattices, can only be done using 'approximate' proofs where one can give only approximate guarantees about the size of the noise-drowning term  $[BBC + 18]$  $[BBC + 18]$ . The noise drowning hugely increases the noise in ciphertexts, and the loose zero-knowledge proof further pushes up parameters if correct ballot decryption is to be ensured.

Unfortunately, all three of these features appear to be crucial in realising the coveted mix-and-decrypt framework in a quantum-secure fashion; the power-of-two ring dimension allows for a highly optimised implementation and the noise-growing and homomorphic operations are fundamental to constructing their mix-net and distributed decryption building blocks. Despite two decades of lattice-based distributed decryption design, no efficient alternative to noise-drowning has been found.

Given the large efficiency gap between classical schemes and the work in [\[ABGS23\]](#page-31-3), it is hard to see how significant efficiency improvements can be found without a new approach.

**Voting from NTRU.** In privacy-preserving protocols, zero-knowledge proofs (ZKPs) are deployed to verify the honest actions of parties, and usually dominate the communication cost. Observation of the recent NIST PQC standards reveals that both the RLWE and RSIS problems are used, however, there is a third long-standing problem which appears in

the Falcon digital signature [\[PFH](#page-36-5)<sup>+</sup>20]; NTRU. Crucially, NTRU ciphertexts contain only a single ring element with three secret elements, giving rise to simpler ZKP relations when compared to their two-component RLWE-based counterparts such as the BGV encryption scheme [\[BGV12\]](#page-32-2), as used in [\[ABGS23\]](#page-31-3), which contains five secret elements. Thus, NTRU might appear to be an attractive candidate problem from which to design a voting protocol.

However, whilst the hardness of the RLWE and RSIS problems are well understood, the picture for NTRU is less clear. Recall, the NTRU problem [\[HPS98\]](#page-34-1). Let  $R_q$  be a polynomial ring of dimension *d* and modulus *q* and sample polynomials *f* and *g* with coefficients from some discrete Gaussian  $D^d_\sigma$ . Informally, the NTRU problem is to recover *f* and *g* given *h*, where  $h = g/f \in R_q$ . In recent years, it has been shown that NTRU is vulnerable to a unique attack when defined for so-called 'overstretched' parameters [\[ABD16,](#page-31-5) [CJL16\]](#page-33-3) i.e. when the modulus *q* is very large compared to *d*. Whilst a line of recent works [\[KF17,](#page-35-3) [DvW21\]](#page-34-5) has made progress in understanding the parameters for which this attack applies, it is not clear how the size of the secrets  $f$  and  $g$  (parametrized by  $\sigma$ ) influence the feasibility of the attack. Thus, designs using large parameters as found in privacy-preserving lattice constructions tend to use the RLWE and RSIS problems for which such behaviour is well understood.

#### **1.1 Our Contribution**

We propose an electronic voting protocol in the mix-and-decrypt paradigm based on the RLWE and NTRU lattice assumptions. We construct each building block from the ground up by presenting an NTRU-RLWE-based verifiable distributed decryption scheme and verifiable mix-net. Moreover, via an in-depth analysis of the NTRU problem, we provide a concrete description of the hardness of the NTRU problem for general secret sizes. We demonstrate the significance of this relation in allowing optimal parameter selection for our scheme and other NTRU-RLWE-based works in which large parameters are necessary. Finally, we give an efficient implementation of our voting scheme demonstrating significant efficiency gains over the state-of-the-art in both communication and computational cost.

**Verifiable Mix-Net from NTRU.** We present a verifiable mix-net for NTRU ciphertexts comprising a series of shuffle servers that each apply a secret permutation to the set of input ciphertexts. As long as at least one shuffle server is honest, the set of input ciphertexts cannot be pair-wise matched to the set of output ciphertexts. Our mix-net is simpler than the one in [\[ABGS23\]](#page-31-3) owing to the single-element NTRU ciphertexts which yield a cleaner protocol than two-element BGV ciphertexts do. Furthermore, one proves knowledge of fewer secret objects when applying ZKPs for verifiability.

**Verifiable Distributed Decryption from NTRU.** We present a distributed decryption protocol based on a variant of the NTRUEncrypt scheme of Steinfeld and Stehlé [\[SS11\]](#page-37-5), proving its security using both the RLWE and NTRU assumptions. This allows for more favourable parameters owing to a computationally secure public NTRU key (vs. a statistically secure one in [\[SS11\]](#page-37-5)). We then apply an exact zero-knowledge proof (ZKP) in order to prove the well-formedness of decryption shares. In particular, this proof proves knowledge of the large noise drowning term needed to prevent leakage of the decryption key and does so in an *exact* fashion. That is, our ZKP (which is a modification of the one by Bootle et al. [\[BLNS21\]](#page-32-3)) proves a tight bound on the size of the noise drowning term. To our knowledge, this is the first exact amortized ZKP of a 'large' secret vector for lattice relations and may be of independent interest. We note that while this makes the proof of distributed decryption larger, it allows for a less restrictive correctness condition, leading to better global parameters throughout the scheme, more than making up for any additional communication cost incurred by this proof.

Scheme	Ciphertexts	Shuffle	Dist. Dec.	Total
[ABGS23] [KB]	80	370	157	2188
Our [KB]	15	130	85	875
$[{\rm ABGS23}]$ ${\rm [ms]}$	0.74	261	138	1182
$Our$ [ms]	0.20	62	328	576

<span id="page-4-0"></span>**Table 1:** Per vote comparison to [\[ABGS23\]](#page-31-3) of ciphertexts, shuffle proofs, decryption proofs, and overall with four servers. Shuffles are sequential, while decryption is done in parallel.

**NTRU Security Analysis.** We build upon the work of Ducas and van Woerden [\[DvW21\]](#page-34-5), on NTRU hardness, to analyse the so-called 'overstretched attack' against NTRU when the norm of the secrets grows with respect to the dimension and modulus. We stress that [\[DvW21\]](#page-34-5) does give an asymptotic fatigue point for general NTRU but only a concrete relation for ternary secrets. Employing the scripts provided in [\[DvW21\]](#page-34-5), our analysis shows that when we increase the standard deviation  $\sigma$ , then  $q$  can be increased with the *square* of this increase before reaching the fatigue point. Concretely, for  $\sigma$  and ring dimension *d* our experiments suggest a fatigue point for modulus *q* given by the following expression

$$
q = 0.0058 \cdot \sigma^2 \cdot d^{2.484}.
$$

Note, by following a similar asymptotic analysis to that in [\[DvW21\]](#page-34-5), we confirm that the influence of  $\sigma$  on the fatigue point must indeed manifest only in the leading constant and not in the exponent of *d*.

To demonstrate the importance of this quadratic relationship, we recompute parameters for the recent (partially) blind signature by del Pino and Katsumata [\[dPK22\]](#page-34-6), improving its efficiency compared to the original scheme, which uses ternary secrets. Most significantly, for this work, the fatigue relation's quadratic nature allows parameters to reach the required security level without needing to increase the ring dimension used in our voting protocol (which would significantly impact performance).

**A New Lattice-Based E-Voting Design from NTRU.** Our main contribution is presenting a new lattice-based e-voting protocol following the standard mix-and-decrypt framework which also supports general ballots. Our design combines our NTRU-based verifiable mix net and distributed decryption schemes. Moreover, we call on our analysis of the NTRU problem to choose fine-tuned concrete parameters. Crucially, when choosing the NTRU secret keys, we can drop the ring dimension down to 2048 from 4096 and modulus down to 59 bits from 78 bits as used in [\[ABGS23\]](#page-31-3) whilst maintaining a 128-bit security level. This would not have been possible without the quadratic nature of the fatigue relation. We provide an efficient  $C++$  implementation of our design.

Overall, we reduce the voting protocol's communication by 2*.*5× and computation by  $2\times$  over [\[ABGS23\]](#page-31-3), see Table [1](#page-4-0) for a comparison and Section [5](#page-27-0) for more details. It is interesting to note that, when compared to their classically secure counterparts, quantum-safe replacements typically come with a  $30\times$  communication cost (e.g. ECDH vs CRYSTALS Kyber/ML-KEM). Comparing our voting scheme to ElGamal-based schemes often used in practice, we incur a cost of at most  $20\times$  in ciphertext size, suggesting that our design may be approaching what can be optimally achieved.

#### **1.2 Related Works**

**Lattice-Based Electronic Voting.** In [\[ABGS23\]](#page-31-3), the authors provide a verifiable mix-net and verifiable distributed decryption protocol based on BGV, showing for the first time that lattice-based electronic voting can be practical for real-world systems. We build directly upon their framework and conduct a more detailed comparison in Section [5.](#page-27-0) This work utilises the verifiable shuffle of known commitment openings by  $[ABG^+21]$  $[ABG^+21]$ ; a building block we adopt<sup>[3](#page-5-0)</sup>. del Pino et al. [\[dPLNS17\]](#page-34-3) gives a practical scheme based on homomorphic counting, but it does not scale well for systems with more complex ballots.

A shuffle by [\[CMM19\]](#page-33-4) was implemented in [\[FWK21\]](#page-34-4); however, it is less efficient than [\[ABGS23\]](#page-31-3). More theoretical works include [\[HMS21\]](#page-34-7), [\[Str19\]](#page-37-6), and [\[CGGI16\]](#page-33-5), but none of these are efficient enough to be considered for practical deployment. Moreover, [\[CMM19,](#page-33-4) [FWK21,](#page-34-4) [HMS21\]](#page-34-7) do not consider the decryption of ballots, which would heavily impact the parameters of the protocols in practice. Finally, [\[BHM20\]](#page-32-4) gives a fast decryption mix-net, but it cannot achieve universal verifiability and is thus unsuitable for real-world elections.

**NTRU Cryptanalysis.** The most relevant work analysing NTRU fatigue is that of Ducas and van Woerden [\[DvW21\]](#page-34-5). It is important to acknowledge that this sits atop a line of work in recent years. The concurrent works [\[ABD16,](#page-31-5) [CJL16\]](#page-33-3) showed, for the first time, that NTRU security is more subtle than simply finding a notably short vector in a lattice. These works exploit the specific algebraic structure of the NTRU lattice to gain an advantage on standard lattice reduction for so-called 'overstretched' parameter regimes.

This work was closely followed by Kirchner and Fouque [\[KF17\]](#page-35-3), who showed that improved attacks were, in fact, only due to the geometric existence of an unusually dense sublattice of large dimension within the NTRU lattice. Moreover, their analysis concludes that *q* larger than  $d^{2.783+o(1)}$  already lies in the overstretched range (for ternary secrets). This bound was improved upon by the work of [\[DvW21\]](#page-34-5) as discussed in Section [4.](#page-21-0)

#### **1.3 Paper Organization**

We begin in Section [2](#page-6-0) by introducing some background material including notation, the NTRU, RSIS, and RLWE lattice assumptions, and the necessary building blocks used in our e-voting design; NTRU encryption, and the BDLOP commitment scheme.

In Section [3](#page-10-0) we present our electronic voting scheme. Section [3.1](#page-10-1) provides an overview of the well-established mix-and-decrypt framework. Section [3.2](#page-11-0) introduces the core, passivelysecure e-voting construction  $\Pi_{\text{PVote}}$ . This is included to aid the reader's intuition before presenting the full scheme. Section [3.3](#page-12-0) contains the full, actively-secure construction  $\Pi_{\text{AVote}}$ whose constituent algorithms are detailed in Figs. [5](#page-15-0) and [6.](#page-16-0) This subsection also makes explicit, the implicit verifiable mixing  $\Pi_{AMix}$  and verifiable distributed decryption  $\Pi_{ADDec}$ building blocks at the core of our design. The section is rounded off with a security analysis of the ΠAMix and ΠADDec building blocks. We dedicate Section [3.4](#page-14-0) to providing the details of zero-knowledge proofs used in our actively secure voting scheme.

Before we can set concrete parameters for our voting scheme, Section [4](#page-21-0) takes a necessary interlude to closely examine the NTRU assumption, providing a fatigue point relation for *general* NTRU secrets (Eq. [\(3\)](#page-24-0)) supported by experimental data displayed in Figs. [7](#page-25-0) and [8.](#page-25-1) This section closes with a discussion of the implications of Eq. [\(3\)](#page-24-0) for existing NTRU-based constructions in the literature.

<span id="page-5-0"></span><sup>3</sup>We remark that in an unpublished work by Jonathan Bootle, Vadim Lyubashevsky, and Antonio Merino-Gallardo (shared over private communication), they found a flaw in the shuffle proof by Aranha et al. [\[ABG](#page-31-2)+21, [ABGS23\]](#page-31-3) that we build upon. However, they also propose a solution similar to the product proof by Costa, Martínez, and Morillo [\[CMM19\]](#page-33-4), where the verifier sends two more public challenges at the start of the protocol, which are incorporated in the proofs of linearity that follows. This change is needed for soundness, but it does not impact the performance of the shuffle.

### <span id="page-6-0"></span>**2 Preliminaries**

Here we detail the essential tools employed in our constructions. We recall standard lattice results and necessary cryptographic building blocks. We begin with some notation.

**Notation.** For a set *S* and distribution  $D$ , " $\leftarrow$  *S*" and " $\leftarrow$  *D*" denote the processes of uniformly sampling from *S* and sampling from (or executing) *D*, respectively. We denote by Perm $[i]$  the set of permutations of the integers  $\{1, ..., i\}$ .

**Adversarial Model.** We assume a static, active adversary who has full control of corrupted parties including access to their internal tapes and the ability to determine outputs. When analysing the security of our voting scheme, properties relating to ballot privacy are proven assuming all but one shuffle server and one decryption server are corrupt<sup>[4](#page-6-1)</sup>. Properties relating to integrity (correctness) hold even if all parties are corrupt.

We assume a trusted setup whereby a single trusted entity creates the public key under which votes are encrypted and secret key shares that are passed to decryption servers. This is common in many voting systems but we note that one could use the techniques of [\[RST](#page-37-7)<sup>+</sup>22] to create a distributed key generation for NTRU.

While our work constructs and implements a voting scheme from quantum-safe assumptions, we do not claim that it is post-quantum secure. Particularly, we do not prove security in the Quantum Random Oracle Model (QROM). See [\[ABGS23,](#page-31-3) Appendix B] for a more detailed discussion on this distinction as it relates to the building blocks we use.

#### **2.1 Lattices**

**The Ring**  $\mathbb{Z}[x]/(x^d + 1)$ . Consider the rings  $R = \mathbb{Z}[x]/\phi$  and  $R_q = \mathbb{Z}_q[x]/\phi$ , where  $\phi = (x^d + 1)$  for *d* an integer power of 2 and *q* a prime. Elements in both rings are polynomials of degree at most  $d-1$ , with those in the latter ring having coefficients between  $-(q-1)/2$  and  $(q-1)/2$ . We denote elements of Z and R by lower-case letters, vectors in  $R^k$  by bold lower-case letters, and matrices in  $R^{(k \times \ell)}$  by bold upper-case letters. For a positive real  $\sigma$ , let  $D_{\mathbb{Z}^d,\sigma}$  denote the discrete Gaussian distribution over  $\mathbb{Z}^d$ . To make the notation simple, we denote  $a \leftarrow D_{\sigma}$  to mean that the coefficient vector of  $a \in R_q$  is sampled from  $D_{\mathbb{Z}^d, \sigma}$ . For  $a, b \in R$ , we have that  $||ab||_{\infty} \le ||a||_1 \cdot ||b||_{\infty}$  and  $||ab||_{\infty}$  ≤  $||a||_2 \cdot ||b||_2$ . Let  $S_{\nu}$  denote the set of all elements  $a \in R$  such that the absolute norm is  $||a||_{\infty} \leq \nu$ .

We use the following standard results for Gaussian vectors:

<span id="page-6-2"></span>**Lemma 1** (Tail Bounds [\[MR04,](#page-36-6) [Lyu12\]](#page-36-7)). For any real  $t > 0$  and  $t' > 1$ , we have

$$
\Pr[x \leftarrow D_{\mathbb{Z}^n, \sigma} : ||x||_{\infty} > t\sigma] < 2n \cdot 2^{-\frac{\log e}{2} \cdot t^2},
$$
  

$$
\Pr[x \leftarrow D_{\mathbb{Z}^n, \sigma} : ||x||_2 > t'\sigma\sqrt{n}] < 2^{n \cdot (\frac{\log e}{2}(1 - t'^2) + \log t')}.
$$

<span id="page-6-1"></span><sup>&</sup>lt;sup>4</sup>In many real-world designs, each server may perform both a shuffling and decryption operation and thus privacy holds if at least one of these servers is honest

**Rejection Sampling.** In lattice-based cryptography in general, and in our zero-knowledge protocols in particular, we would like to output vectors  $\mathbf{z} = \mathbf{y} + \mathbf{v}$  such that **z** is independent of **v**, and hence, **v** is masked by the vector **y**. Here, **y** is sampled according to a Gaussian distribution  $\mathcal{N}^k_{\sigma}$  with standard deviation  $\sigma$  and we want the output vector **z** to be from the same distribution. The procedure is shown in Figure [1.](#page-7-0)

Here, 1*/M* is the probability of success, and *M* is computed as

$$
\max \frac{\mathcal{N}_{\sigma}^{k}(\mathbf{z})}{\mathcal{N}_{\mathbf{v},\sigma}^{k}(\mathbf{z})} \le \exp \left[ \frac{24\sigma \|\mathbf{v}\|_{2} + \|\mathbf{v}\|_{2}^{2}}{2\sigma^{2}} \right] = M \tag{1}
$$

where we use the tail bound from Lemma [1,](#page-6-2) saying that  $|\langle \mathbf{z}, \mathbf{v} \rangle| < 12\sigma \|\mathbf{v}\|_2$  with probability at least  $1 - 2^{-100}$ . Hence, for  $\sigma = 11 \|\mathbf{v}\|_2$ , we get  $M \approx 3$ . This is the standard way to choose parameters, see e.g. [\[BLS19\]](#page-32-5). However, if the procedure is only done once for the vector **v**, we can decrease the parameters slightly, to the cost of leaking only one bit of information about **v** from given **z**.

<span id="page-7-0"></span>In [\[LNS21\]](#page-35-4), Lyubashevsky et al. suggest to require that  $\langle \mathbf{z}, \mathbf{v} \rangle \geq 0$ , and hence, we can set  $M = \exp(||v||_2/2\sigma^2)$ . Then, for  $\sigma = 0.675||v||_2$ , we get  $M \approx 3$ . In Fig. [1,](#page-7-0) we use the pre-determined bit *b* to denote if we only use **v** once or not, with the effect of rejecting about half of the vectors before the sampling of uniform value  $\mu$  in the case  $b = 1$  but allowing a smaller standard deviation.

**Figure 1:** Rejection Sampling.

**The NTRU Problem.** We give the historical presentation of the NTRU problem as it is more convenient for our analysis in Section [4.](#page-21-0) We note that some works refer to this problem as the 'search/decisional short polynomial ratio' problem [\[LTV12,](#page-36-8) [SXY18\]](#page-37-8) Furthermore, one can consider the so-called 'module' NTRU problem [\[CKKS19,](#page-33-6) [CPS](#page-33-7)<sup>+</sup>20], which considers the ratio of matrices of polynomials **F** and **G**. Our analysis and applications can naturally be extended to the module setting, so for ease of presentation, we use the basic (polynomial) NTRU formulation [\[HPS98\]](#page-34-1).

<span id="page-7-1"></span>**Definition 1** (Search/Decision NTRU). Let  $q > 2$  be a prime, *d* be the ring dimension, and  $D_{\sigma_{\text{NTRU}}}$  be a distribution over  $R_q$ . Sampling  $(f, g) \leftarrow D_{\sigma_{\text{NTRU}}}^2$  with rejection if f is not invertible in  $R_q$ , define  $h = g/f \in R_q$ . The search-NTRU<sub>q,d, $\sigma_{\text{NTRU},t}$ </sub> problem is, given *h*, to recover any pair  $(f', g')$  such that  $h = g'/f' \in R_q$  and  $||f', g'||_2 \le t \cdot \sigma_{\text{NTRU}}$ . The decision-NTRU<sub>q,d, $\sigma_{\text{NTRU}}$  problem is, given *h*, to decide if *h* is computed as  $h = g/f$  for</sub>  $(f, g) \leftarrow D^2_{\sigma_{\text{NTRU}}}$  or if *h* is sampled uniformly from  $R_q$ .

**The RLWE and RSIS Problems.** We define the standard lattice-hardness problems over rings [\[Ajt96,](#page-31-0) [Reg05,](#page-37-1) [LPR10\]](#page-36-2).

**Definition 2** (Ring Learning with Errors)**.** Let *q >* 2 be a prime, *d* be the ring dimension,  $D_{\sigma_{\text{RWE}}}$  be a distribution over  $R_q$ , and A a PPT algorithm that makes at most *Q* oracle

queries. Then the advantage of A in solving the ring learning with errors  $RLWE_{d,q,Q,\sigma_{RLWE}}$ problem is defined as

$$
\mathsf{Adv}_{d,q,Q,\sigma_{\mathsf{RLWE}}}^{\mathsf{RLWE}}(\mathcal{A}) = \left| \Pr[\mathcal{A}^{\mathcal{O}_{\mathsf{RLWE}}}(d,q,\sigma_{\mathsf{RLWE}}) \to 1] - \Pr[\mathcal{A}^{\mathcal{O}_{\$}}(d,q,\sigma_{\mathsf{RLWE}}) \to 1] \right|,
$$

where oracles  $\mathcal{O}_{\text{RLWE}}$  and  $\mathcal{O}_{\text{S}}$  are defined as

- $\circ$   $\mathcal{O}_{\text{RLWE}}$ : Samples  $a \leftarrow R_q$ ,  $(s_1, s_2) \leftarrow D^2_{\sigma_{\text{RLWE}}}$ , and then output  $(a, as_1 + s_2);$
- $\mathcal{O}_s$ : Samples  $(a, b) \leftarrow R_a \times R_a$ , and then output  $(a, b)$ .

**Definition 3** (Ring Short Integer Solutions)**.** Let *q >* 2 be a prime, *d* be the ring dimension,  $\|\cdot\|$  a norm, and  $\beta \in \mathbb{R}^+$  a positive integer. The RSIS<sub>d,q, $\beta$ </sub> problem is, given a uniformly random  $a \in R_q$ , find  $s_1, s_2 \in R_q$  such that  $as_1 + s_2 = 0 \in R_q$  and  $0 \le ||s_1, s_2|| \le \beta$ .

#### <span id="page-8-2"></span>**2.2 Building Blocks**

**NTRU Encryption.** In this work, we will use the provably secure variant of the NTRU cryptosystem first presented by Steinfeld and Stehlé in [\[SS11\]](#page-37-5). This scheme relies on the hardness of both the RLWE and NTRU assumptions. Note we make two minor modifications to ensure perfectly correct decryption: (1) encryption randomness is sampled from a bounded distribution, and (2) the secret keys *f* and *g* are rejected unless their  $\ell_2$  norm is below a given bound. When sampled accordingly, this limitation has only a negligible effect on the completion probability of the key generation algorithm and the entropy of resulting keys.

**Setup.** Let  $p \ll q$  be primes and *d* a power of two which define the rings  $R_p$  and  $R_q$ . Messages lie in  $R_p$ . Let  $\sigma_{\text{NTRU}} \in \mathbb{R}^+$  and  $D_{\sigma_{\text{NTRU}}}$  a discrete Gaussian distribution over *R* with standard deviation  $\sigma_{\text{NTRU}}$ ,  $t \in (1, 2]$  and  $\nu \in \mathbb{N}$ . Let the setup parameters be  $\mathsf{sp} = (d, p, q, \sigma_{\text{NTRU}}, t, \nu)$ . The encryption scheme is described in Fig. [2.](#page-8-0)

<span id="page-8-0"></span>**Key Generation** KeyGen<sub>NTRU</sub>(sp). Given input  $sp = (d, p, q, \sigma_{NTRU}, t, \nu)$ :

- 1.  $f, g \leftarrow D_{\sigma_{\text{NTRU}}}$ ; if  $f \notin R_q^{\times}$  or  $f \not\equiv 1 \in R_p$ , resample.
- 2. If  $||f||_2, ||g||_2 > t$ . √ *d* · *σ*NTRU, restart.
- 3. Return  $sk = f$ ,  $pk = h := g/f \in R_q$ .

**Encryption** Enc<sub>NTRU</sub> $(m, \text{pk})$ . Given message  $m \in R_p$  and public key  $\text{pk} = h$ :

- 1. Sample encryption randomness  $s, e \leftarrow S_{\nu}$ .
- 2. Return ciphertext  $c = p \cdot (hs + e) + m \in R_q$ .

**Decryption** Dec<sub>NTRU</sub> $(c, sk)$ . Given ciphertext *c* and key  $sk = f$ :

1. Return message  $m = (f \cdot c \mod q) \mod p$ .

**Figure 2:** Adapted NTRUEncrypt [\[SS11\]](#page-37-5).

<span id="page-8-1"></span>**Lemma 2** (NTRUEncrypt Security). Let  $p \cdot d \cdot t \cdot \sigma_{\text{NTRU}}(2\nu + 1/2) < |q/2|$ . Then the *encryption scheme in Fig. [2](#page-8-0) is (perfectly) correct. Moreover, assuming the hardness of the*  $NTRU_{q,d,\sigma_{NTRU}}$  and  $RLWE_{d,q,Q,\chi}$  problems, the scheme is IND-CPA secure.

The proof of Lemma [2](#page-8-1) closely follows the one given in [\[SS11\]](#page-37-5) and a similar scheme (also assuming the NTRU assumption) is presented in [\[LTV12\]](#page-36-8). We provide a sketch proof of our scheme for completeness.

*Proof.* We first consider correctness. Examine the decryption operation  $(f \cdot c \mod q)$ mod p. For messages to be recovered correctly, we need that no modular reduction occur modulo *q* inside the bracket. That is, for perfectly correct decryption we require  $||f \cdot c||_{\infty} \leq |q/2|$ . We have that

$$
||f \cdot c||_{\infty} \le p||gs||_{\infty} + p||fe||_{\infty} + ||fm||_{\infty}
$$
  
\n
$$
\le p \cdot ||g||_1 \cdot \nu + p \cdot ||f||_1 \cdot \nu + ||f||_2 \cdot \sqrt{d} \cdot ||m||_{\infty}
$$
  
\n
$$
\le p \cdot \sqrt{d} \cdot ||g||_2 \cdot \nu + p \cdot \sqrt{d} \cdot ||f||_2 \cdot \nu + ||f||_2 \cdot \sqrt{d} \cdot ||m||_{\infty}
$$
  
\n
$$
\le p \cdot dt \cdot \sigma_{\text{NTRU}} \cdot (2\nu + 1/2),
$$

as assumed in the statement of the lemma. IND-CPA security is proven using a hybrid argument, in two steps:

- 1. The hardness of the  $\text{NTRU}_{q,d,\sigma_{\text{NTRU}}}$  allows the simulator to change the public key  $h = g/f \in R_q$  to a uniformly sampled *h*.
- 2. The simulator next changes the challenge ciphertext  $c^* = p \cdot (hs + e) + m \in R_q$  to  $c^* = u + m \in R_q$ , where *u* is sampled uniformly at random from  $R_q$ . This change is indistinguishable by the  $RLWE_{d,q,1,\chi}$  assumption.

In this final hybrid, the advantage of the adversary is exactly  $1/2$  since  $c^*$  is uniform over *R<sup>q</sup>* independent of the message *m*. Thus, we have

$$
\mathsf{Adv}^{\mathsf{IND}\text{-}\mathsf{CPA}}(\mathcal{A}) \leq \mathsf{Adv}_{q,d,\sigma_{\mathsf{NTRU}},t}^{\mathsf{decision}\text{-}\mathsf{NTRU}}(\mathcal{A}) + \mathsf{Adv}_{d,q,1\chi}^{\mathsf{RLWE}}(\mathcal{A})
$$

**The BDLOP Commitment Scheme.** Here we recall the BDLOP commitment scheme from  $[BDL+18]$  $[BDL+18]$ . For simplicity, we present the scheme instantiated over rings instead of modules, committing to only one ring element at a time. The scheme is parametrised by  $B_{\text{Com}}, \sigma_{\text{Com}} \in \mathbb{R}^+$ , and challenge space C whose difference set is  $\overline{C}$ .

Setup : Samples uniformly random  $a_1, a_2, a_3$  from  $R_q$  and outputs the public commitment key  $pk_C$  defined as:

$$
\mathsf{pk}_{\mathsf{C}} = \begin{bmatrix} \vec{a}_1 & 0 \\ \vec{a}_2 & 1 \end{bmatrix} = \begin{bmatrix} 1 & a_1 & a_2 & 0 \\ 0 & 1 & a_3 & 1 \end{bmatrix}.
$$

 $Com(\mathsf{pk}_C, x)$ : On input a public commitment key  $\mathsf{pk}_C$  and an element *x* in  $R_q$ , samples a vector  $\vec{r} \in R_q^3$  such that  $\|\vec{r}\|_{\infty} \leq B_{\text{Com}}$ , and computes the commitment as:

$$
\text{com} = \begin{bmatrix} \vec{c}_1 \\ \vec{c}_2 \end{bmatrix} = \begin{bmatrix} 1 & a_1 & a_2 & 0 \\ 0 & 1 & a_3 & 1 \end{bmatrix} \begin{bmatrix} r_1 \\ r_2 \\ r_3 \\ x \end{bmatrix} = \llbracket x \rrbracket.
$$

It outputs the commitment com and the opening  $d = (x, \vec{r}, 1)$ .

 $Open(\mathsf{pk}_C, \mathsf{com}, d)$ : On input a public commitment key  $\mathsf{pk}_\mathsf{C}$ , the commitment com and the opening  $d = (x, \vec{r}, f)$  where  $f \in \overline{C}$ . It verifies:

$$
f \cdot \text{com} \stackrel{?}{=} \begin{bmatrix} 1 & a_1 & a_2 & 0 \\ 0 & 1 & a_3 & 1 \end{bmatrix} \begin{bmatrix} r_1 \\ r_2 \\ r_3 \\ f \cdot x \end{bmatrix},
$$

and  $\forall i \in [3] : ||r_i||_2 \overset{?}{\leq} 4 \cdot \sigma_{\mathsf{Com}}$ √ *d.* It outputs 1 if the relations hold and 0 otherwise.

**Lemma 3** (Commitment Security [\[BDL](#page-32-6)<sup>+</sup>18])**.** *The BDLOP commitment scheme is hiding if the RLWE problem is hard for vectors of*  $\ell_{\infty}$  *norm*  $B_{\text{Com}}$  *over a lattice of dimension* 2 · *d and binding if the RSIS problem is hard for vectors of*  $\ell_2$  *norm*  $16\sigma_{\text{Com}}\sqrt{\kappa d}$  *over a lattice of dimension*  $2 \cdot d$ *.* 

### <span id="page-10-0"></span>**3 The Voting Scheme**

A *cryptographic voting scheme* is usually defined in terms of the algorithms for election setup, casting ballots, and counting cast ballots. We need algorithms for shuffling and distributed decryption to model the counting process accurately. To make such a scheme verifiable (actively secure), we also need a mechanism to enforce the fact that the encryption, shuffling, and decryption algorithms are computed honestly. This section presents an NTRUbased voting protocol in the well-established 'mix-and-decrypt' paradigm, comprising new verifiable distributed decryption and mix-net protocols. We refer to Chapter 14 in the book by Gjøsteen [\[Gjo22\]](#page-34-8) and Appendix H in the full version of Aranha et al. [\[ABGS22\]](#page-31-6) for a more thorough description of e-voting schemes.

#### <span id="page-10-1"></span>**3.1 Voting Scheme Overview**

**Setup Phase.** A trusted party runs the key generation algorithm for the PKE scheme with distributed decryption. In this work, we will assume a trusted key generation and leave the design of a distributed key generation algorithm for NTRU to future work, as a trusted setup is typical for many voting schemes<sup>[5](#page-10-2)</sup>. The generated public parameters sp are given to every participant, while the decryption key shares  $d\mathbf{k}_i$  are distributed amongst the decryption servers.

**Casting Phase.** Each voter instructs their voting device to cast their chosen ballot. The device encrypts the ballot under the public key pk to create a ciphertext *c*, and it computes a *ballot proof*. The standard way to do this is to use a verifiable encryption scheme such as the one presented in [\[LNP22\]](#page-35-5), proving that the submitted ciphertext contains a genuine ballot in zero-knowledge. We remark that it is indeed required for the voters to prove plaintext knowledge to ensure security of the voting scheme, to prevent attacks such as copying and re-randomizing ballots from other voters.

**Counting Phase.** This is divided into three sequential processes. First, encrypted ballots are passed through a series of shuffle servers.

The  $\xi_1$  shuffle servers  $S_1, \ldots, S_{\xi_1}$  consecutively run the shuffle algorithm of the set of encrypted ballots  $\{c_i^{(k-1)}\}$ , passing the shuffled and re-encrypted ballots  $\{c_i^{(k)}\}$  to the next shuffle server. They also generate a shuffle proof which anyone can verify. We may refer to this whole shuffle process as the *mix-net*.

<span id="page-10-2"></span><sup>&</sup>lt;sup>5</sup>One could adapt the techniques of  $[RST+22]$  $[RST+22]$  to create a distributed key generation for NTRU.

<span id="page-11-1"></span>

**Figure 3:** The voting protocol with verifiable mix-net and distributed decryption, adapted from [\[ABGS23,](#page-31-3) Figure 1] with shuffle servers  $S_i$  and decryption servers  $\mathcal{D}_j$ .

Each of the  $\xi_2$  decryption servers  $\mathcal{D}_j$  receives the output of each shuffle server and verifies the corresponding shuffle proofs. Only after verifying each proof does a decryption server begin decryption.  $\mathcal{D}_j$  then computes a set of partial decryption shares  $\{ds_{ij}\}\$ , one for each of the ciphertexts. Finally, it creates a proof of decryption to guarantee that it computed its shares correctly. Each decryption server passes its shares to the combining algorithm Comb.

The Comb algorithm performs the task of recovering the ballots. The Comb algorithm verifies the decryption proofs after receiving all decryption shares from decryption servers. If all decryption proofs are verified, the ballots are recovered by combining the decryption shares.

A schematic of these processes, in the malicious setting, is shown in Fig. [3.](#page-11-1) This figure is adapted from [\[ABGS23\]](#page-31-3) and shows the voting protocol beginning with input of a set of encrypted ballots and finishing with a set of ballots in plaintext. We note that some works consider an auditor who verifies the processes at each step by checking the proofs provided. This is a stylistic design choice. For the purposes of this paper, it is helpful to think of the proofs as providing verifiability of each phase by any third party and by the component servers before carrying out their roles.

#### <span id="page-11-0"></span>**3.2 Passively Secure Scheme**

Here we present our passively secure voting scheme. Whilst our ultimate goal is to give a verifiable (actively secure) voting scheme, we first isolate the core, passively secure skeleton for clarity of presentation. We begin by defining the algorithms and syntax of this construction.

**Definition 4** (Passively Secure Voting Scheme). Let *τ* be the number of voters,  $ξ_1$  the number of shuffle servers, and  $\xi_2$  the number of decryption servers. A passively secure cryptographic voting scheme ΠPVote consists of five algorithms (KeyGen*,* Cast*,* Mix*,* DDec*,* Comb).

KeyGen(sp)  $\rightarrow$  (pk, sk, {dk<sub>j</sub>}<sub>j∈[ξ<sub>2</sub>]) : On input setup parameters sp, it returns a public</sub> encryption key pk, a secret key sk and a set of *ξ*<sup>2</sup> secret decryption key shares  $\{\mathsf{dk}_j\}_{j\in[\xi_2]}$ .

Cast( $\mathsf{pk}, v$ )  $\rightarrow$  *c* : On input a public key **pk** and vote *v* it returns an encrypted ballot *c*.

- $\text{Mix}(\{c_i\}_{i\in[\tau]}) \rightarrow \{\hat{c}_i\}_{i\in[\tau]}$ : On input a set of encrypted ballots  $\{c_i\}_{i\in[\tau]}$  it returns a set of encrypted ballots  $\{\hat{c}_i\}_{i \in [\tau]}.$
- $\text{DDec}_j(\{c_i\}_{i \in \tau}, \mathsf{dk}_j) \to \{\mathsf{ds}_{i,j}\}$ : On input a set of encrypted ballots  $\{c_i\}_{i \in [\tau]}$  and a decryption key  $dk_j$ , it returns a set of decryption shares  $ds_j = \{ds_{i,j}\}_{i \in [\tau]}$ .
- Comb $(\{c_i\}_{i \in [\tau]}, \{\text{ds}_j\}_{j \in [\xi_2]}) \rightarrow \{v\}_{i \in [\tau]}: \text{ On input a set of encrypted balls } \{c_i\}_{i \in [\tau]} \text{ and }$ a set of decryption shares  $\{\mathsf{ds}_j\}_{j \in [\xi_2]}$ , it outputs a set of votes  $\{v\}_{i \in [\tau]}$ .

We instantiate the algorithms, present our passively secure voting scheme and give an overview in Fig. [4.](#page-13-0)

**Setup.** Let  $p \ll q$  be primes and *d* a power of two which define the rings  $R_p$  and *R*<sub>*q*</sub>. Votes lie in *R*<sub>*p*</sub>. Let  $\sigma_{\text{NTRU}}, B_{\text{Dec}}, B_{\text{Drown}} \in \mathbb{R}^+, t \in (1, 2],$  and  $\nu, \tau, \xi_1, \xi_2 \in \mathbb{N}$ . Let  $sp = (d, p, q, \sigma_{\text{NTRU}}, t, \nu, \tau, \xi_1, \xi_2).$ 

#### <span id="page-12-0"></span>**3.3 Actively secure scheme**

We present our actively secure (verifiable) voting scheme. This can be seen as a natural extension of the passive protocol  $\Pi_{\text{PVote}}$  by adding verifiability to the mixing and distributed decryption processes. This is done by applying the zero-knowledge proofs of Section [3.4](#page-14-0) so that the outputs of Mix<sub>A</sub> and DDec<sub>A</sub> now include a proof of shuffle  $\pi_S$  and a proof of decryption  $\pi_D$  respectively. Note the use of 'A' in algorithm/protocol suffixes to indicate the actively-secure variant (as opposed to those using 'P' i.e. passively-secure variants).

Now, any third party can verify that the mixing and distributed decryption processes were carried out correctly without compromising the privacy or integrity of the voting system. As usual, we assume a trusted dealer for key generation and leave the construction of an NTRU-based distributed key generation for other applications to future work.

This construction implicitly defines a verifiable mixing with verifiable distributed decryption from NTRU. We consider these to be of independent interest and give an overview as stand-alone protocols.

**Verifiable Mixing.** Our aim here is, given a set of input ciphertexts, to generate a new set of ciphertexts that decrypts to the same set of plaintexts. Crucially, input-output ciphertext correspondence must be obscured. Additionally, we would like any third party to verify that this process has been performed correctly without compromising the privacy of the mix.

For this, we apply the proof of  $[ABC^{\dagger}21]$ , which allows one to prove a shuffle of openings of the lattice commitments in Section [2.2.](#page-8-2) We denote this proof system  $\Pi_{\text{Short}}$ . Since NTRU ciphertexts only contain a single element, we can import their scheme without modification where the committed messages are ciphertexts. We also employ the  $\Pi_{\text{SMALL}}$  proof systems described in Section [3.4](#page-14-0) to prove that the new ciphertext noise is sufficiently bounded. At a high level, our verifiable mixing of NTRU ciphertexts *c*1*, ..., c<sup>τ</sup>* re-randomises the input ciphertexts and then permutes their order where the permutation is only known to the shuffle server:

- 1. The mixing server creates encryptions  $c'_1, ..., c'_{\tau}$  of 0 and commits to these as  $[[c'_i]]$  for each  $i \in [\tau]$ . Run the  $\Pi_{\text{SMALL}}$  protocol to prove that each committed ciphertext is honestly computed.
- 2. Adding the original ciphertexts *c<sup>i</sup>* to these commitments homomorphically yields commitments  $[\hat{c}_i]$  to ciphertexts with the same plaintext as in  $c_1, ..., c_{\tau}$ , now with fresh randomness.

<span id="page-13-0"></span>KeyGen(sp). On input system parameters sp:

- 1.  $(\mathsf{sk} = f, \mathsf{pk} = h) \leftarrow \mathsf{KeyGen}_{\mathsf{NTRU}}(d, p, q, \sigma_{\mathsf{NTRU}}, t).$
- 2. For  $j \in [\xi_2 1]$ ,  $\mathsf{dk}_j \leftarrow \mathcal{U}(R_q)$  and set  $\mathsf{dk}_{\xi_2} = \mathsf{sk} \sum_{j=1}^{\xi_2 1} \mathsf{dk}_j \mod q$ .
- 3. Return ( $pk, sk$ ) and key shares  $\{dk_j\}_{j \in [\xi_2]}$ .

Cast(pk, *v*). On input the public key pk and a vote  $v \in R_p$ :

- 1. Compute  $c = \mathsf{Enc}_{\mathsf{NTRU}}(\mathsf{pk}, v)$ .
- 2. Return encrypted ballot *c*.

 $Mix({c_i}_{i \in [\tau]})$ . On input encrypted ballots  ${c_i}_{i \in [\tau]}$ :

- 1. For each  $i \in [\tau]$ , compute  $c_i' = \text{Enc}_{\text{NTRU}}(\text{pk}, 0)$ .
- 2. For each  $i \in [\tau]$ , compute  $\hat{c}_i = c_i + c'_i \mod q$ .
- 3. Sample a random permutation  $\pi \leftarrow \text{Perm}[\tau]$ .
- 4. Return re-encrypted ballots  $\{\hat{c}_{\pi(i)}\}_{i\in[\tau]}.$

DDec<sub>*j*</sub>({*c<sub>i</sub>*}<sub>*i*∈*τ*</sub> *,* dk<sub>*j*</sub>). On input a set of encrypted ballots {*c*}<sub>*i*∈*τ*</sub> and a decryption key share dk*<sup>j</sup>* :

- 1. For each  $i \in [\tau]$ , sample  $E_{ij} \leftarrow S_{B_{\text{Down}}}$  and compute share  $ds_{ij} = dk_j \cdot c_i + p \cdot E_{ij}$ mod *q*.
- 2. Return the set of decryption shares  $ds_j = \{ds_{ij}\}_{i \in [\tau]}$ .

Comb( ${c_i}_{i \in [\tau]}$ ,  ${ds_j}_{j \in [\xi_2]}$ ). On input encrypted ballots  ${c_i}_{i \in [\tau]}$  and decryption shares  ${ds_j = {ds_{ij}}_{i \in [\tau]} }_{j \in [\xi_2]}$ 

- 1. For each  $i \in [\tau], v_i = \left(\sum_{j \in [\xi_2]} \textsf{ds}_{ij} \mod q\right) \mod p$ .
- 2. Return the set of votes  $\{v_i\}_{i \in [\tau]}.$

**Figure 4:** The passively-secure voting scheme Π<sub>PVote</sub>.

3. The server now reveals the openings  $\hat{c}_i$  in a randomly permuted order and runs the ΠShuf protocol to prove that these are indeed a permutation of the correct openings of the commitments.

We note that verification of the shuffle proof should be done before any ballot decryption begins. This can be seen as a first step of the DDec algorithm or as part of a global verification process carried out by an auditor. For simplicity of presentation and since this is covered in [\[ABGS23\]](#page-31-3), we omit this from the full protocol.

**Verifiable Distributed Decryption.** Our aim here is, given a set of input ciphertexts, to generate a set of decryption shares to extract the encrypted plaintexts when all the shares are combined. Furthermore, each decryptor must prove they decrypted their decryption share correctly using their secret key share. Therefore, in the active setting, the public key contains a commitment  $[\![d_k]\!]$  to each secret key share  $d_k$ , and each decryptor holds an opening to precisely one of the commitments. The verifiable distributed decryption

protocol works as follows:

- 1. For each  $i \in [\tau]$ , the decryptor samples a noise value  $E_{ij} \leftarrow S_{B_{\text{Drown}}}$ , computes a decryption share  $ds_{ij} = dk_j \cdot c_i + p \cdot E_{ij}$  and commits to the noise as  $[E_{ij}]$ .
- 2. For each  $i \in [\tau]$ , it uses the  $\Pi_{\text{Lin}}$  protocol to prove that the linear decryption equation above is computed honestly with respect to  $[\mathsf{dk}_i]$  and  $[E_{ij}]$ .
- 3. For each  $i \in [\tau]$ , it uses the  $\Pi_{\text{Bnd}}$  protocol to prove that  $[[E_{ij}]]$  is an honestly created commitment and the committed value is bounded by  $B_{\text{Drown}}$ .

We wish to emphasise the importance of our  $\Pi_{\text{Bnd}}$  proof system.  $\Pi_{\text{Bnd}}$  is a modification of the ZKP by Bootle et al. in [\[BLNS21\]](#page-32-3)). Crucially, it proves a tight bound on the size of the noise drowning term  $E_{ij}$ . To our knowledge, this is the first exact ZKP of a 'large' secret vector for lattice relations and may be of independent interest. Though a more costly proof, proving an exact bound on  $E_{ij}$  will lead to more efficient global parameters in Section [5.](#page-27-0) We remark that one might consider using the LNP proof system of [\[LNP22\]](#page-35-5) for  $\Pi_{\text{Bnd}}$ . However, proofs arising from the LNP framework scale linearly with the witness while our design saves a square root factor by comparison. Furthermore, LNP is designed for proving 2-norms directly and one would need to perform some witness encoding to prove infinity norms, further reducing efficiency.

**Setup.** Let  $p \ll q$  be primes and *d* a power of two which define the rings  $R_p$  and  $R_q$ . Votes lie in  $R_p$ . Let  $\sigma_{\text{NTRU}}, B_{\text{Dec}}, B_{\text{Drown}}, B_{\text{Com}}, B_{\text{Small}} \in \mathbb{R}^+, t \in (1, 2],$  and  $\nu, \tau, l, \xi_1, \xi_2 \in \mathbb{N}$ . Let  $sp = (d, p, q, \sigma_{\text{NTRU}}, t, \nu, \tau, l, \xi_1, \xi_2, B_{\text{Dec}}, B_{\text{Drown}}, B_{\text{Com}}).$ 

#### <span id="page-14-0"></span>**3.4 Zero-Knowledge Proofs**

We present the proof systems needed in the actively secure voting protocol. We wish to highlight, in particular, how we adapt the amortised proof of boundedness  $\Pi_{\rm BND}$  as compared to previous works [\[ABGS23\]](#page-31-3). The crucial observation here is that whilst we get slightly larger proofs there, the *exact* guarantees provided by the proof allow for better parameters to be chosen for the overall voting scheme. This leads to a net reduction in communication costs.

**Amortized Proof of Shortness.** In Step 2 of the shuffle, we use  $\Pi_{\text{Small}}$  to prove that we have committed to well-formed encryptions of zero. The protocol  $\Pi_{\text{Small}}$  produces a proof that a batch of equations  $\vec{As}_i = \vec{t}_i$  for  $i \in [\ell]$  is satisfied for a set of secret vectors  $\vec{s}_i$ with  $\ell_{\infty}$  norm bounded by *ν*. The exact relation for the proof system is:

$$
\mathcal{R}_{\text{SMALL}} := \left\{ (x, w) \middle| \begin{array}{c} x := (\mathsf{pk}_C, \{\mathsf{com}_i\}_{i \in [\ell]}) \ \land w := (\{d_i = (u_i, \vec{r}_i, f_i)\}_{i \in [\ell]}): \\ \forall i \in [\ell] : \ \|u_i\|_{\infty} \leq \nu \ \land \ \mathsf{Open}(\mathsf{pk}_C, \mathsf{com}_i, d_i) \end{array} \right\}.
$$

The proof of shortness  $\pi_{\text{SMALL}}$  is quite involved, combining error-correcting codes, Merkle trees, Lagrange interpolation and proximity testing, and we refer to [\[ABGS23\]](#page-31-3) for details. For batch size  $\ell$  of ternary secret vectors, the proof size is given in [\[ABGS23,](#page-31-3) Eq. (1)] as

$$
(3vd + (3l + 2)\eta) \log_2 q + 2\lambda \eta (1 + \log_2 \gamma)
$$
 bits,

using an  $[\gamma, \mu, \iota]$  Reed-Solomon Code with code-length  $\gamma$ , message length  $\mu$  and minimal distance *ι* where  $\mu = d(k+2) + \eta \leq \gamma < q$  for encoding randomness of length  $\eta$ .  $\lambda$  is the security parameter. The soundness error of the proof is given as

$$
2 \cdot \max\left\{2\left(\frac{\mu'}{\gamma-\eta}\right)^{\eta}, \frac{1}{q-\ell}+\left(1-\frac{\mu'-\mu}{6\gamma}\right)^{\eta}, 2 \cdot \left(1-\frac{2(\mu'-\mu)}{3\gamma}\right)^{\eta}, \frac{18\ell}{q-\ell}\right\},\right\}
$$

for a choice of message length  $\mu'$  such that  $\mu \leq \mu' \leq \gamma < q$ .

<span id="page-15-0"></span>KeyGen<sub>A</sub>(sp). On input system parameters sp:

- 1. Run (pk*,*sk)*,* {dk*j*}*j*∈[*ξ*2] ← KeyGen(sp).
- 2. For  $j \in [\xi_2]$ , compute the commitments and openings ( $[\![dk_j]\!], \vec{r}_{dk_j}$ )  $\leftarrow$  Com( $dk_j$ ).
- 3. Return  $pk_A = (pk, [dk_1], ..., [dk_{\xi_2}])$ ,  $sk_A = sk$ , and key shares  $\{\mathsf{dk}_{A,j} = \big(\mathsf{dk}_j, \vec{r}_{\mathsf{dk}_j}\big)\}_{j \in [\xi_2]}.$

 $\textsf{Cast}_A(\textsf{pk}_A, v)$ . On input a public key  $\textsf{pk}_A$  and a vote *v* in  $R_p$ , retrieving  $\textsf{pk}$  from  $\textsf{pk}_A$ :

1. Return  $c \leftarrow$  Cast(pk, v).

 $\text{Mix}_{\mathsf{A}}(\{c_i\}_{i \in [\tau]})$ . On input a set of encrypted ballots  $\{c_i\}_{i \in [\tau]}$ :

- 1. For  $i \in [\tau]$ , compute  $c'_i \leftarrow \text{Enc}_{\text{NTRU}}(\text{pk}, 0)$  using encryption randomness  $(s'_i, e'_i)$ .
- 2. For  $i \in [\tau]$ , commit to  $c'_i$  as  $com'_i := [c'_i] \leftarrow Com(pk_C, c'_i)$  where  $\vec{r}_{c'_i}$  is the commitment randomness used. Then denoting

$$
\mathbf{A}_{\mathsf{M}} = \begin{bmatrix} 1 & a_{1,1} & a_{1,2} & 0 & 0 \\ 0 & 1 & a_{2,2} & p h & p \end{bmatrix},
$$

and  $\mathbf{s}_{c_i'} = [\vec{r}_{c_i'}, s_i', e_i']^T$  compute  $\pi_{\mathsf{Small}_i} \leftarrow \Pi_{\mathsf{Small}_i}$  for matrix  $\mathbf{A}_{\mathsf{M}},$  input vector  $\mathbf{s}_{c_i'},$ targets  $com'_i$  and bound  $B_{Small}$ . Set  $\pi_{Small} := {\pi_{Small_i}}_{i \in [\tau]}$ .

- 3. For  $i \in [\tau]$ , compute  $\hat{c}_i = c_i + c'_i$ . Sample  $\pi \leftarrow \text{Perm}([\tau])$ , and compute  $\pi$ Shuf ←  $\Pi$ Shuf with input commitments  $\{\llbracket \hat{c}_i \rrbracket \}_{i \in [\tau]},$  randomness  $\{\vec{r}_{c_i'}\}_{i \in [\tau]},$ ciphertexts  $\{\hat{c}_i\}_{i \in \tau}$ , and permuted ciphertexts  $\{\hat{c}_{\pi(i)}\}_{i \in [\tau]}$ .
- 4. Return  $(\{\hat{c}_{\pi(i)}\}_{i\in[\tau]}, \pi_{\mathcal{S}}),$  where  $\pi_{\mathcal{S}} = (\{\mathsf{com}'_i\}_{i\in[\tau]}, \pi_{\mathsf{Small},\tau_{\mathsf{Shuf}}}).$

**Figure 5:** ΠAVote key generation, casting, and shuffle.

**Proof of Shuffle.** In Step 3 of the shuffle, we use  $\Pi_{\mathsf{Shuf}}$  to prove that a set of committed values is a permutation of public values.

The committed values will be the  $\hat{c}_i$  values in our context. The verifier can construct these from the  $c_i$  and the  $\llbracket c'_i \rrbracket$ . The public values are the  $\hat{c}_i$ . The proof then convinces the verifier that output ciphertexts are a genuine permutation of the re-randomized input ciphertexts. The exact relation for the proof system is:

$$
\mathcal{R}_{\text{SHUF}} := \left\{(x,w) \left| \begin{array}{c} x := (\{(\text{com}_i, \bar{u}_i)\}_{i \in [\tau]}) \ \wedge \, w := (\{d_i = (u_i, \vec{r_i}, f_i)\}_{i \in [\tau]}, \rho) : \\ \rho \in \text{Perm}[\tau] \ \wedge \ \forall i \in [\tau] : \ u_i = \bar{u}_{\rho(i)} \wedge \ \text{Open}(\text{pk}_C, \text{com}_i, d_i) \end{array} \right\}.
$$

The proof of shuffle  $\pi_{\text{SHUF}}$  is computed as follows [\[ABG](#page-31-2)<sup>+</sup>21, Section 4]:

- 1. Hash the statement to get a uniform value and then convert all commitments and messages to  $u'_i$  and  $\bar{u}'_i$  (the commitments are additionally homomorphic).
- 2. For all  $i \in [\tau-1]$ , sample random values  $\theta_i$  and commit to random linear combinations of the form  $[\![D_i]\!] = [\![\theta_{i-1} \cdot u'_i + \theta_i \cdot \bar{u}'_i]\!]$  (where  $\theta_0 = \theta_\tau = 0$ ).
- 3. Hash the commitments to get a uniform challenge *β*. Then for all  $i \in [\tau]$  compute  $s_i$ to solve the linear system for *β*.
- 4. For all  $i \in [\tau]$ , compute proofs of linearity for the commitment equations of the form  $[[D_i]] = s_{i-1}[[u'_i]] + s_i \cdot \bar{u}'_i$  (where  $s_0 = \beta$  and  $s_\tau = (-1)^\tau \beta$ ).

<span id="page-16-0"></span> $\text{DDec}_{A,j}(\{c_i\}_{i\in[\tau]}, \text{dk}_{A,j})$ . On input a set of ciphertexts  $\{c_i\}_{i\in[\tau]}$  and decryption key share  $\mathsf{dk}_{A,j} = \big(\mathsf{dk}_j, \vec{r}_{\mathsf{dk}_j}\big)$ :

- 1. For  $i \in [\tau]$ , sample  $E_{ij} \leftarrow S_{B_{\text{Down}}}$ , and compute  $ds_{ij} = dk_j \cdot c_i + p \cdot E_{ij}$ .
- 2. For  $i \in [\tau]$ , compute  $([E_{ij}], \vec{r}_{E_{ij}}) \leftarrow \textsf{Com}(E_{ij}, \textsf{pk}_{\textsf{C}})$  and use the  $\Pi_{\textsf{Lin}}$  protocol to compute a proof  $\pi$ <sub>Lin<sub>ij</sub> for the linear relation  $ds_{ij} = dk_j \cdot c_i + p \cdot E_{ij}$ .</sub>
- 3. Apply the amortized proof of boundedness  $\Pi_{\text{Bnd}}$ , to create a proof  $\pi_{\text{Bnd}}$  that, for all  $i \in [\tau], ||E_{ij}||_{\infty} \leq B_{\text{Drown}}$  and  $||\vec{r}_{E_{ij}}||_{\infty} \leq B_{\text{Com}}$ .
- 4. Return  $ds_j := (\{ds_{ij}\}_{i \in [\tau]}, \pi_{\mathcal{D}}),$  where  $\pi_{\mathcal{D}} = (\{\llbracket E_{ij} \rrbracket\}_{i \in [\tau]}, \{\pi_{\mathsf{Lin}_{ij}}\}_{i \in [\tau]}, \pi_{\mathsf{Bnd}}).$

Comb<sub>*A*</sub>({*c<sub>i</sub>*}<sub>*i*∈[*τ*]</sub>, {ds<sub>*j*</sub>}<sub>*j*∈[*ξ*<sub>2</sub>]</sub>). On input encrypted ballots {*c<sub>i</sub>*}<sub>*i*∈[*τ*]</sub> and decryption shares  $\{\mathsf{ds}_j\}_{j\in[\xi_2]}\colon$ 

- 1. Parse  $ds_j$  as  $(\{ds_{ij}\}_{i\in[\tau]}, \pi_{\mathcal{D}_j})$ , and verify the proofs  $\pi_{\text{Lin}_{ij}}$  and  $\pi_{\text{Bnd},ij}$ , returning  $\perp$  if either fails to verify.
- 2. Compute

$$
v_i = \left(\sum_{j \in [\xi_2]} \mathsf{ds}_{ij} \mod q\right) \mod p.
$$

3. Return the set of votes  $\{v_i\}_{i \in [\tau]}.$ 

The verifier accepts if all proofs of linearity are valid. This proof  $\pi_{\text{SHUE}}$  consists of one ring element, one commitment and one proof of linearity per shuffled element. Using the proof of linearity  $\pi_{\text{L}N}$  from above, the size of  $\pi_{\text{ShUF}}$  is  $\tau d(2k \log_2(4\sigma_{\text{L}N}) + 3 \log_2 q)$  bits.

We use the following challenge set in our proof of linearity  $\Pi_{\mathsf{Lin}}$ .

**Challenge Set.** Let *κ* be such that  $\binom{d}{k} \cdot 2^{\kappa} > 2^{\lambda}$  and define  $\mathcal{C}_{\kappa} = \{c \in R_q \mid ||c||_{\infty} = 0\}$  $1 \wedge ||c||_1 = \kappa$  and  $\overline{\mathcal{C}}_{\kappa} = \{c - c' \mid c, c' \in \mathcal{C}_{\kappa} \wedge c \neq c'\}.$ 

**Proof of Linearity.** In Step 2 of DDec, we prove well-formedness of the linear decryption share. The protocol  $\Pi_{\text{Lin}}$  produces a proof that a committed value *v* is a multiple of another committed value *u* with respect to a public scalar *g*. In our setting, we will prove  $[[E_{ij} - p^{-1}ds_{ij}] = -p^{-1}c_i[[dk_j]].$ 

The exact relation for the proof system is:

$$
\mathcal{R}_{\text{LIN}} := \left\{ (x, w) \middle| \begin{array}{c} x := (\mathsf{pk}_C, \mathsf{com}_u, \mathsf{com}_v, g) \land \\ w := (d_u = (u, \vec{r}_u, f_u), d_v = (v, \vec{r}_v, f_v)) : \\ u = g \cdot v \land \mathsf{Open}(\mathsf{pk}_C, \mathsf{com}_u, d_u) \land \mathsf{Open}(\mathsf{pk}_C, \mathsf{com}_v, d_v) \end{array} \right\}.
$$

The proof of linearity  $\pi_{\text{LN}}$  is computed as follows [\[BDL](#page-32-6)<sup>+</sup>18]:

- 1. Sample vectors  $\vec{y}_u$  and  $\vec{y}_v$  of length *k* over  $R_q$  according to  $D_{\sigma_{\text{LIN}}}$  and compute  $\vec{w}_u = \vec{a}_1 \cdot \vec{y}_u$  and  $\vec{w}_v = \vec{a}_1 \cdot \vec{y}_v$  and  $t = g \cdot \vec{a}_2 \cdot \vec{y}_u - \vec{a}_2 \cdot \vec{y}_v$ .
- 2. Hash  $(\vec{w}_u, \vec{w}_v, t)$  to c in  $\mathcal{C}_{\kappa}$ , and compute  $\vec{z}_u = \vec{y}_u + c \cdot \vec{r}_u$ ,  $\vec{z}_v = \vec{y}_v + c \cdot \vec{r}_v$ .
- 3. Rejection sample with respect to  $(\vec{y}_u, \vec{z}_u)$ , and  $(\vec{y}_v, \vec{z}_v)$ . If it outputs 1 then output  $\pi_{\text{LIN}} = (c, \vec{z}_u, \vec{z}_v)$  and otherwise restart by sampling new  $(\vec{y}_u, \vec{y}_v)$ .

The verifier checks if  $||\vec{z}_u, \vec{z}_v||_2 \leq 2\sigma_{\text{LIN}}$ √  $k \cdot d$  and if the hash of  $(\vec{a}_1 \cdot \vec{z}_u - c \cdot c_{u,1}, \vec{a}_1 \cdot c)$  $\vec{z}_v - c \cdot c_{v,1}, g \cdot \vec{a}_2 \cdot \vec{z}_u - \vec{a}_2 \cdot \vec{z}_v + c_{v,2} + g \cdot c_{u,2}$  equals c. It outputs 1 if all checks verify, and otherwise it outputs 0.

Using the improved rejection sampling techniques from [\[LNS21\]](#page-35-4), we set  $\sigma_{\text{LN}} = B_{\text{Com}}$ . *κ* √ d. The size of  $\pi_{\text{LIN}}$  is  $2kd \log_2(4\sigma_{\text{LIN}})$  bits.

**Amortized Proofs of Boundedness.** In Step 3 of DDec, we use  $\Pi_{\text{Bnd}}$  to prove boundedness on noise drowning terms  $E_{ij}$ . The main idea is that we use a bit-decomposition  $E_i$ to produce a long vector with small entries, allowing the application  $\Pi_{\mathsf{Small}}$  to prove an exact bound on  $E$ . We define  $\Pi_{\text{Bnd}}$  as an adapted version of the  $\Pi_{\text{Smal}}$  protocol.

The previous work by Aranha et al. [\[ABGS23\]](#page-31-3) used the amortised relaxed proofs by Baum et al.  $[BBC + 18]$  $[BBC + 18]$  to get smaller proof sizes at the cost of slightly increasing the overall parameters of the voting scheme because of the slack inherent in the proof system. In practice, this leads to a slightly larger modulus *q* but does not impact the ring dimension *d*. However, in our setting, we get better parameters in practice for the whole scheme when giving exact proofs of boundedness, even though the proofs themselves are larger. The precise relation of the proof system, with batch size  $\ell'$  and secret vectors bounded in the  $\ell_{\infty}$  norm by  $B_{\text{Drown}}$ , is:

$$
\mathcal{R}_{\text{BND}} := \left\{ (x, w) \middle| \begin{array}{c} x := (\mathsf{pk}_C, \{\mathsf{com}_i\}_{i \in [\ell']}) \ \land w := (\{d_i = (u_i, \vec{r}_i, f_i)\}_{i \in [\ell']}) : \\ \forall i \in [\ell'] : \ \|u_i\|_{\infty} \leq B_{\text{Drown}} \ \land \ \mathsf{Open}(\mathsf{pk}_C, \mathsf{com}_i, d_i) \end{array} \right\}.
$$

Since ΠSmall is a proof system that scales with the number of possible values of the secret vectors, we use bit decomposition techniques to limit a blow-up in terms of running time, memory usage and proof size, to the cost of proving knowledge of longer secret vectors.

Any integer *E* between 0 and *q* can be represented in base *b* as  $E = [b_0, b_1, \ldots, b_\zeta] \circ [1, b, \ldots, b^\zeta]$ for unique coefficients  $b_i$  between 0 and  $b-1$  and  $\zeta = \lceil \log_b q \rceil - 1$  where  $\circ$  is the dot product. This can be naturally extended to vectors, matrices and modules, particularly for our commitment matrix *A*. Since the commitment randomness is already short, we only need to decompose the last element in the secret vector, and we can do so in the following way (note that we abuse notation, where after  $(*)$  the elements before | are in  $R_q$  and the elements after are in  $\mathbb{Z}_q$ , but any element in  $R_q$  can be represented in  $\mathbb{Z}_q^d$ ):

$$
\mathbf{A}_{ij}\mathbf{s}_{ij} = \begin{bmatrix} 1 & a_{1,1} & \mathbf{a}_{1,2} & |0] \ 0 & 1 & \mathbf{a}_{2,2} & |1] \end{bmatrix} \begin{bmatrix} \vec{r}_{E_{ij}} \\ E_{ij} \end{bmatrix}
$$

$$
\stackrel{(*)}{=} \begin{bmatrix} 1 & a_{1,1} & \mathbf{a}_{1,2} & |0 & \dots & 0 \\ 0 & 1 & \mathbf{a}_{2,2} & |1 & \dots & b^{\zeta} \end{bmatrix} \begin{bmatrix} \vec{r}_{E_{ij}} \\ E_{0ij} \\ \vdots \\ E_{\zeta ij} \end{bmatrix} = \bar{\mathbf{A}}_{ij}\bar{\mathbf{s}}_{ij}.
$$

Here, the ring element  $E_{ij}$  is decomposed, and elements  $E_{0ij}, \ldots, E_{\zeta ij}$  have integer values between 0 and  $b-1$ . We note that these statements are equivalent and that the length of  $\overline{\mathbf{A}}_{ij}$  is  $d(k+\zeta+1)$  over  $\mathbb{Z}_q$  instead of  $d(k+2)$ .

Finally, we use the  $\Pi_{Small}$  protocol to prove ternary secret values as above but with a tweak: the public matrix input to the protocol is  $\mathbf{A}_{ij}$  instead of  $\mathbf{A}_{ij}$ , and we change the coefficient values that we are checking for in the proof. For the first  $d \cdot k$  values we are checking for  $(0, 1, -1)$  coefficients but for the next  $d(\zeta + 1)$  values we are checking for  $(0,1,2)$  coefficients instead (this is a minor tweak of line 3 in [\[ABGS23,](#page-31-3) Figure 5] that does not impact the performance of the protocol in any way, these values are initially arbitrary to the proof system). Since the other secret parts are ternary, we have that  $\zeta = \lceil \log_3 B_{\text{Drown}} \rceil - 1.$ 

#### **3.5 Security Analysis**

We analyse the security of our verifiable voting scheme presented in Figs. [5](#page-15-0) and [6.](#page-16-0) We examine the shuffle and distributed decryption protocols individually and prove their security. We emphasise that this is the standard approach in modern e-voting schemes based on mix-nets and is similar to the protocol used by Swiss Post for voting in Switzerland (they have a mix-net with key-switching so that there is only one decryption server needed in the end, while we only do mixing and then provide a distributed decryption protocol; these approaches are equivalent). Then, these standard primitives can be composed into a secure voting scheme as described in Chapter 14 in the book by Gjøsteen [\[Gjo22\]](#page-34-8) and Appendix H in the full version of Aranha et al. [\[ABGS22\]](#page-31-6). Hence, we inherit their arguments for integrity, privacy and verifiability of the overall e-voting scheme. Our main contribution is more efficient building blocks that fit into this gold standard framework for e-voting, leading to a lattice-based e-voting scheme with improved performance over the state-of-the-art by Aranha et al. [\[ABGS23\]](#page-31-3). We *do not* propose a new model for e-voting.

**Verifiable Mixing Protocol.** We analyse the security of the verifiable shuffle protocol implicitly defined by the tuple of algorithms  $\Pi_{AMix} := (KeyGen_A, Cast_A, Mix_A, Dec_{NTRU}).$ We conduct this analysis against the set of standard definitions in Appendix [A](#page-39-0) for verifiable mixing. Thus, our security results refer to 'mixing' properties, but we emphasise that this is another term for shuffling in this context. Note that security is analysed concerning a single shuffle server. In the context of our voting protocol, ballot privacy requires that at least one shuffle server is honest. We say that  $\Pi_{AMix}$  is *secure* if it satisfies the properties of mixing completeness, mixing soundness, and mixing simulatability.

**Lemma 4** ( $\Pi_{AMix}$  Completeness). If the protocols  $\Pi_{Small}$  and  $\Pi_{Shuf}$  are complete then  $\Pi_{AMix}$  *always terminates. Moreover, if the input ciphertexts*  $c_i$  *have noise bounded by*  $B_{Dec}$ , *and the total noise added in* Mix<sub>A</sub> *is bounded by*  $B_{\text{Mix}}$  *such that*  $(B_{\text{Mix}} + B_{\text{Dec}}) \leq \lfloor q/2 \rfloor$ *, then the output ciphertexts*  $\hat{c}_i$  *decrypt to the same messages as*  $c_i$ *.* 

*Proof.* Since  $\Pi_{\mathsf{Small}}$  and  $\Pi_{\mathsf{Shuf}}$  are complete, the protocol will finish and the verifier will accept the output of the mix. Since  $(B_{\text{Mix}} + B_{\text{Dec}}) \leq \lfloor q/2 \rfloor$ , it follows that decryption is correct. Thus,  $\Pi_{AMix}$  is complete.  $\Box$ 

**Lemma 5** (ΠAMix Soundness)**.** *Suppose the input ciphertexts, output ciphertexts, and commitments in the shuffle are*

$$
(c_1,\ldots,c_{\tau},\hat{c}_1,\ldots,\hat{c}_{\tau},\llbracket c_1'\rrbracket,\ldots,\llbracket c_{\tau}'\rrbracket),
$$

*respectively. Let*  $Ext_1$  *be a knowledge extractor for the protocol*  $\Pi_{Small}$  *with success probability*  $\epsilon_1$  *and let* Ext<sub>2</sub> *be a knowledge extractor for the protocol*  $\Pi_{\text{Shuf}}$  *with success probability*  $\epsilon_2$ *. Then we can construct a knowledge extractor*  $\textsf{Ext}_0$  *that succeeds with probability*  $\epsilon_0 \leq \epsilon_1 \cdot \epsilon_2$ *in extracting (1) a permutation*  $\pi$ , (2) encryption randomness  $s'_{i}$ ,  $e'_{i}$  for  $i \in [\tau]$ , and (3) *commitment randomness*  $\mathbf{r}_{c_i'}$  *for*  $i \in [\tau]$  *such that* 

- The  $\llbracket c'_i \rrbracket$  are commitments, using commitment randomness  $\mathbf{r}_{c'_i}$ , to ciphertexts of 0*, say*  $c'_i$ , with encryption randomness  $s'_i, e'_i$ .
- $||(s'_i, e'_i)||_{\infty} \leq B_{\text{Mix}}$
- $\hat{c}_{\pi(i)} = c_i + c'_i$

*Proof.* First, note that the conditions above exactly constitute a correct mix so that if an adversary provides us

 $(c_1, \ldots, c_{\tau}, \hat{c}_1, \ldots, \hat{c}_{\tau}, [\llbracket c'_1 \rrbracket, \ldots, [\llbracket c'_{\tau} \rrbracket),$ 

and we are able to extract as in the statement of the Lemma, then the adversary must have performed a correct mix. The main observation is that both extractors  $Ext_1$  and Ext<sub>2</sub> must succeed. Before verifying the shuffle proof  $\pi$ <sub>Shuf</sub>, the verifier sets

$$
[\![\hat{c}_i]\!] := [\![c_i]\!]_0 + [\![c'_i]\!]_{r_{c'_i}}
$$

Here 0 and  $r_{c_i'}$  are the commitment randomness values resp. The verifier then runs the  $\pi$ <sub>Shuf</sub> verification checks against this set of commitments. This ensures that, if the proof verifies, the commitments  $com_i$  in the shuffle proof statement use exactly the same commitment randomness as used in the commitments to the  $c_i'$ .

If the extractor  $\textsf{Ext}_1$  succeeds, we are able to extract  $\tau$  randomness vectors  $\textbf{s}_{c'_i}$  bounded by  $B_{\mathsf{Small}}$ , which gives us the randomness for both the commitments and ciphertexts used in the protocol. However, if the adversary is able to cheat in  $\Pi_{\mathsf{Shuf}}$  then the output ciphertexts will be different to the ciphertexts we extract from  $\Pi_{\mathsf{Small}}$ , and hence, we have not yet extracted all objects as in the Lemma.

If the extractor Ext<sub>2</sub> succeeds, we are able to extract both the permutation  $\pi$  and  $\tau$ randomness vectors  $\mathbf{r}_{c_i'}$  used in the commitments. However, if the adversary is able to cheat in  $\Pi_{\mathsf{Small}}$  then the output ciphertexts might have more noise than  $(B_{\text{Dec}} + B_{\text{Mix}})$  and lead to decryption failures, and hence, we have not yet extracted all objects in the Lemma.

We conclude that it is both necessary and sufficient that both extractors succeed at the same time to extract witnesses with respect to the same set of output ciphertexts and proofs to extract both the randomness used to encrypt, the randomness used to commit, and the permutation used to shuffle, and hence, to extract all objects in the Lemma. We thus conclude that  $\epsilon_0 \leq \epsilon_1 \cdot \epsilon_2$ .

 $\Box$ 

**Lemma 6** (Π<sub>AMix</sub> Simulatability). *Suppose the protocols* Π<sub>Small</sub> *and* Π<sub>Shuf</sub> *are honestverifier zero-knowledge and that* Com *is hiding, Then there exists a simulator for* ΠAMix *such that for any distinguisher*  $\mathsf{Adv}_0$  *with advantage*  $\epsilon_0$ *, there exist adversaries*  $\mathsf{Adv}_1$ ,  $\mathsf{Adv}_2$ *against the HVZK of the* Π<sub>Small</sub> *and* Π<sub>Shuf</sub> *protocols, and an adversary* Adv<sub>3</sub> *against hiding of the commitment scheme with advantage*  $\epsilon_3$ *, with advantages*  $\epsilon_1$ *,* $\epsilon_2$ *, and*  $\epsilon_3$  *respectively such that*  $\epsilon_0 \leq \epsilon_1 + \epsilon_2 + \epsilon_3$ . The runtime of Adv<sub>1</sub>, Adv<sub>2</sub>, Adv<sub>3</sub> are the same as of Adv<sub>0</sub>.

*Proof.* The simulator is given a set of input ciphertexts and a set of output ciphertexts from an honest mix. The simulator simulates the zero-knowledge proofs  $\Pi_{\mathsf{Small}}$  and  $\Pi_{\mathsf{Shuf}}$ using the appropriate simulators and replaces the commitments to the ciphertexts with commitments to zero.

The claim about the simulator follows from a hybrid argument. In the following games, we denote by  $E_i$  the event that the adversary wins in Game  $i$ . *Game 0.* This is the real-world protocol. We have that

$$
\Pr[E_0] = \epsilon_0.
$$

*Game 1.* Here, we replace the  $\Pi_{\mathsf{Shuf}}$  arguments with simulated arguments. We have that, by the honest verifier zero-knowledge property of  $\Pi_{\mathsf{Shuf}},$ 

$$
|\Pr[E_1] - \Pr[E_0]| \le \epsilon_1.
$$

*Game 2.* Here we replace the  $\Pi_{Small}$  by simulated arguments. We have that by the honest verifier zero-knowledge of ΠSmall

$$
|\Pr[E_2] - \Pr[E_1]| \le \epsilon_2.
$$

*Game 3.* Here we replace the commitments to ciphertexts with commitments to zero. We have that by the hiding property the commitment scheme that

$$
|\Pr[E_3] - \Pr[E_2]| \le \epsilon_3.
$$

After the changes, we are left with a simulator for the actively secure protocol that outputs a proof that is independent of any secrets, and so the advantage  $\epsilon_0$  of the adversary  $\mathsf{Adv}_0$ is thus

$$
\epsilon_0\leq \epsilon_1+\epsilon_2+\epsilon_3,
$$

as claimed.

**Verifiable Distributed Decryption Protocol.** We now analyse the security of the PKE with distributed decryption implicitly defined by the tuple of algorithms  $\Pi_{\text{ADDec}}$  := (KeyGenA*,* CastA*,* DecNTRU*,* DDecA*, ,* CombA). We say that ΠADDec is *secure* if it satisfies the properties of threshold correctness, threshold verifiability, and distributed decryption simulatability. For completeness, we give the full definitions of these notions in Appendix [B.](#page-39-1) Since many of these properties rely on building blocks used in previous works, we provide a proof sketch here and refer the reader to [\[ABGS23\]](#page-31-3) for the full arguments. We will however make parameter constraints explicit to aid in the performance analysis of Section [5.](#page-27-0)

**Lemma 7** (Π<sub>ADDec</sub> Threshold Correctness). *Suppose*  $\Pi_{\text{Lin}}$  *and*  $\Pi_{\text{Bnd}}$  *are complete, and the total noise in each ciphertext*  $(1 + 2^{\text{sec}}/p\xi_2)B_{\text{Dec}}$  *is less than*  $\lfloor q/2 \rfloor$ *, then*  $\Pi_{\text{ADDec}}$  *is threshold correct.*

*Proof.* Examining the threshold correctness, define the predicate  $P_{\mathsf{sk}_{\mathsf{A}}}(\cdot)$  so that  $P_{\mathsf{sk}_{\mathsf{A}}}(c) = 1$ if and only if  $||\mathbf{sk}_{A} \cdot c||_{\infty} < B_{\text{Dec}}$ . Then given a set of adversarially generated ciphertexts  ${c}$ <sub>*i*∈[*τ*]</sub> satisfying  $P_{\mathsf{sk}_A}(c_i) = 1$  for all  $i \in [\tau]$ , we have that  $\left\| \sum_{j \in [\xi_2]} \mathsf{ds}_{ij} \right\|_{\infty} < q/2$  and so the Comb algorithm will return the correct decryption of  $c_i$ . The completeness of  $\Pi_{\text{Lin}}$  and  $\Pi_{\text{Bnd}}$  ensure that the arguments will be accepted, thus,  $\Pi_{\text{ADDec}}$  is threshold correct.  $\Box$ 

**Lemma 8** (Π<sub>ADDec</sub> Threshold Verifiability). Let Adv<sub>0</sub> be an adversary against threshold *verifiability of*  $\Pi_{ADDec}$  *with advantage*  $\epsilon_0$ . Then there exists adversaries Adv<sub>1</sub> and Adv<sub>2</sub> *against soundness for* ΠLin *and* ΠBnd*, respectively, with advantages ϵ*<sup>1</sup> *and ϵ*2*, such that*  $\epsilon_0 \leq \epsilon_1 + \epsilon_2.$ 

*Proof.* As in the definition of threshold verifiability, we only consider ciphertexts such that  $P_{s_{k}}(c) = 1$ . That is, ciphertexts whose noise is bounded by  $B_{\text{Dec}}$ . Note that if Comb accepts a ciphertext for which decryption is incorrect then, for some *j*, no relation  $ds_{ij} = dk_j \cdot c_i + pE_{ij}$  holds for an  $E_{ij}$  of norm at most  $B_{\text{Drown}}$ .

This can happen in one of two ways. Either the proof of the linear relation  $ds_{ij} =$  $dk_i \cdot c_i + pE_{ij}$  is incorrect or the proof of the bound on  $E_{ij}$  is incorrect. In the first case one has an adversary  $\text{Adv}_1$  against the soundness of  $\Pi_{\text{Lin}}$  and in the second case an adversary Adv<sub>2</sub> against the soundness of  $\Pi_{\text{Bnd}}$ .  $\Box$ 

**Lemma 9** (ΠADDec Simulatability)**.** *Suppose* NTRUEncrypt *cryptosystem is* IND*-*CPA *secure,* ΠLin *and* ΠBnd *are honest-verifier zero-knowledge, and* Com *is hiding. Then there exists a simulator such that for any distinguisher* Adv<sub>0</sub> *for this simulator with advantage*  $\epsilon_0$ *, there exists an adversary* Adv<sub>1</sub> *against the HVZK of* Π<sub>lin</sub>*, an adversary* Adv<sub>2</sub> *against the HVZK of* ΠBnd*, and an adversary* Adv<sup>3</sup> *against the hiding of* Com *with advantages*  $\epsilon_1, \epsilon_2, \epsilon_3$  *respectively such that*  $\epsilon_0 \leq \epsilon_1 + \epsilon_2 + \epsilon_3$ *. The runtime of* Adv<sub>1</sub>, Adv<sub>2</sub>*, and* Adv<sub>3</sub> *are the same as of*  $Adv_0$ .

*Proof.* The claim about the simulator follows from a hybrid argument. In the following games, we denote by  $E_i$  the event that that the adversary wins in Game  $i$ .

*Game 0*. This is the real world protocol. We have that

 $\Pr [E_0] = \epsilon_0.$ 

 $\Box$ 

*Game 1*. Here, we replace the  $\Pi_{\text{Lin}}$  arguments with simulated arguments. We have that, by the honest verifier zero-knowledge property of  $\Pi_{\mathsf{Lin}},$ 

$$
|\Pr\left[E_1\right] - \Pr\left[E_0\right]| \le \epsilon_1.
$$

*Game 2*. Here we replace the  $\Pi_{\text{Bnd}}$  by simulated arguments. We have that by the honest verifier zero-knowledge of  $\Pi_{\text{Bnd}}$  that

$$
|\Pr\left[E_2\right] - \Pr\left[E_1\right]| \le \epsilon_2.
$$

*Game 3*. Here we replace the commitments noise  $E_{ij}$  with random commitments. We have that by the hiding property the commitment scheme that

$$
|\Pr\left[E_3\right] - \Pr\left[E_2\right]| \le \epsilon_3.
$$

*Game 4*. Here we replace decryption shares  $ds_{ij}$  with random shares. By the choice of the statistical security parameter sec, which is chosen so that  $ds_{ij}$  is statistically indistinguishable from uniform, we have that

$$
Pr [E_4] = Pr [E_3]|.
$$

After the changes, we are left with a simulator for the actively secure protocol outputting a proof that is independent of any secrets, and so the advantage  $\epsilon_0$  of adversary  $\text{Adv}_0$  is thus bounded by

$$
\epsilon_0 \leq \epsilon_1 + \epsilon_2 + \epsilon_3.
$$

<span id="page-21-0"></span>**4 NTRU Hardness**

Before choosing concrete parameters for implementing our new voting scheme, it is clear that we needed to better understand the NTRU problem's hardness. This section contains that in-depth analysis which informs our parameter choices in Section [5.](#page-27-0)

Research on the security of the NTRU problem has revealed a significant improvement in the performance of lattice reduction algorithms when applied to NTRU lattices for so-called *overstretched* parameters. More precisely, analysis carried out over a series of works [\[ABD16,](#page-31-5) [KF17,](#page-35-3) [LW20\]](#page-36-9) shows this weakening of NTRU occurs when the modulus *q* is very large compared to the ring dimension *d* and when secrets are small. Naturally, these works seek to determine the turning point at which *q* becomes large enough for such attacks to apply. We refer to this as the *fatigue point*.

#### **4.1 Extending the NTRU Analysis**

Until recently, only an asymptotic result was known about the position of the fatigue point, determined by Kirchner and Fouque as  $q = d^{(2.783 + o(1))}$  [\[KF17\]](#page-35-3).

**Ducas-van Woerden Analysis.** In their recent paper, Ducas and van Woerden [\[DvW21\]](#page-34-5) improve on the asymptotic result of Kirchner and Fouque who showed in their analysis that the NTRU lattice, denoted  $\Lambda^{h,q}$ , contains an exceptionally dense sublattice, denoted  $\Lambda^{g,f}$ , of low volume which gives a constraint on the basis profile via Lemma [10](#page-22-0) below<sup>[6](#page-21-1)</sup>. Thus, the fatigue point for ternary secrets is narrowed down to  $q = d^{(2.484 + o(1))}$ . Building on this

 $\Box$ 

<span id="page-21-1"></span> $6$ Ducas and van Woerden [\[DvW21\]](#page-34-5) considers both NTRU (see Definition [1\)](#page-7-1), and the module version of NTRU and use matrix notation in their paper. We continue to use polynomial ring notation to keep this consistent with our notation.

result, the authors perform an average-case analysis (rather than a worst-case bound) based on the volume of the relevant lattices and sublattices to arrive at a concrete prediction of the fatigue point. To facilitate their analysis, they identify two lattice reduction events that distinguish standard regimes from their overstretched counterparts.

- **Secret Key Recovery (SKR):** The event in which a vector as short as the secret key is inserted into the lattice basis.
- **Dense Sublattice Discover (DSD):** The event in which a vector of the dense sublattice is inserted into the basis.

A DSD event has been shown to shortly precede SKR by a cascading of further DSD events or enabling decryption of fresh ciphertexts. A further distinction between DSD events that are triggered at large positions  $\kappa \leq 2d - \beta$  in the basis; DSD-LL (lucky lift), and those triggered at positions  $\kappa = d + k - \beta$  for  $0 < k \ll d$  and BKZ block size  $\beta$ , DSD-PT, in a run of progressive BKZ on NTRU lattices for fixed parameters  $d = 127, \sigma^2 = 2/3$  and several moduli *q*. We redefine them below.

- **DSD-LL:** For a few instances the  $\text{DSD}_\kappa$  event is triggered at large positions  $\kappa$ , up to  $2d - \beta$ . The inserted dense vector **v** is again significantly longer than the secret key, but it has an unexpectedly short projection  $\pi_k(\mathbf{v})$  on the BKZ block  $[\kappa : k\beta]$ .
- **DSD-PT:** The DSD<sub>*k*</sub> event is triggered at positions  $\kappa = d + k \beta$  for  $0 < k \ll d$ . The inserted dense vector **v** is often significantly longer than the secret key, but still shorter than than the *q*-vectors, and the projection of **v**,  $\pi_{\kappa}(\mathbf{v}) < ||\mathbf{b}_{\kappa}^*||$ .

They introduce the new DSD-PT event named after the Pataki and Tural in Lemma [10](#page-22-0) and give an asymptotic analysis in Section 3 of their paper before giving an average-case analysis to construct a concrete estimator and compare this estimate with experiments in Section 4 and Section 5, respectively. The DSD-LL events are found to be a rare occurrence, and they speculate that the DSD-LL events are artefacts of using modest parameters in their experiments and are, for the most part, excluded from their analysis [\[DvW21\]](#page-34-5).

<span id="page-22-0"></span>**Lemma 10** (Pataki and Tural [\[PT08\]](#page-37-9))**.** *Let* Λ *be a d-dimensional lattice with basis*  $\mathbf{b}_0, \ldots, \mathbf{b}_{d-1}$ . For any  $k$  – *dimensional sublattice*  $\Lambda' \subset \Lambda$  *we have* 

<span id="page-22-1"></span>
$$
\text{vol}(\Lambda') \ge \min_J \prod_{j \in J} \|\mathbf{b}_j^*\|^2,
$$

*where J* ranges over the *k*-size subsets of  $\{0, \ldots, d-1\}$  and  $\mathbf{b}_j^*$  is the Gram-Schmidt *orthogonalization of*  $\mathbf{b}_j$ .

Ducas and van Woerden give a concrete average-case estimate for the intersection of lattice volumes and the log-expectation of the volume of the dense NTRU sublattice  $\Lambda^{g,f}$ in Eq. [\(2\)](#page-22-1). They assume that all coefficients of the dense sublattice basis are sampled according to an independent continuous Gaussian distribution with standard deviation *σ*. They prove this estimate in [\[DvW21,](#page-34-5) Section 4.2] and verify these estimates experimentally with variance  $\sigma^2 = 2/3$ .

$$
\mathbb{E}[\ln(\text{vol}(\Lambda^{gf}))] = \frac{1}{2}d(\ln(2\sigma^2) + \psi(d)) + \sum_{i=0}^{d-1} \left[ \psi\left(\frac{2d-i}{2}\right) - \psi(d) \right],\tag{2}
$$

where  $\psi$  is the digamma function.

In [\[DvW21,](#page-34-5) Section 5] they compare their concrete predictions with experiments. They ran progressive BKZ 2.0 with 8 tours on NTRU with parameters  $d = 127, \sigma^2 = 2/3$  for several moduli *q*, accounting for both SKR and DSD-PT events. For BKZ blocksizes  $\beta > 30$ their experiments correspond nicely to their predictions, while for  $\beta \leq 30$  their DSD-PT estimate is slightly pessimistic compared to the experiments. To further verify their fatigue point estimate, they did more experiments in larger, but still feasible dimensions. They found that the concrete estimator for the dense sublattice volume in Eq. [\(2\)](#page-22-1) reasonably follows the observed experiments.

Through careful observation of the occurrence of these events, Ducas and van Woerden use their predictive model to determine the concrete fatigue point of NTRU with ternary secrets to be  $q = 0.004 \cdot d^{2.484}$  for  $d > 100$ . One can use the scripts provided<sup>[7](#page-23-0)</sup> in their work to estimate the concrete hardness of NTRU. We also affirm their predictive model by running real experiments on low-dimensional instances to confirm this relation. It is worth noting that this is not the same NTRU estimator as the one provided in the lattice estimator[8](#page-23-1) maintained by Martin Albrecht which implements the 2016 estimate [\[ADPS16\]](#page-31-7).

**Beyond Ternary Secrets.** The reader may have noticed that the discussion of the fatigue point, thus far, only focuses on the modulus and dimension of the ring. Recalling Definition [1](#page-7-1) reminds us that *f* and *g* need not always be ternary. Indeed, many NTRU-based constructions use secrets with non-ternary coefficients. Let us consider *f* and *g* generated according to a Gaussian distribution  $D_{\sigma}$  of standard deviation  $\sigma$ . For convenience, the analysis of [\[DvW21\]](#page-34-5) models the ternary secret case by sampling  $f, g \leftarrow D_{\sigma}$  with  $\sigma^2 = 2/3$ . Varying  $\sigma$  can model any secret key size, and thus we will herein consider that f and q are always sampled according to some Gaussian  $D_{\sigma}$ . The natural question arises:

#### *Does the choice of (secret size) σ influence the fatigue point, and if so, what is its impact?*

To get some intuition on this, we recall the work of Steinfeld and Stehlé [\[SS11\]](#page-37-5) in which the authors show how selecting  $\sigma$  sufficiently large gives rise to a public key  $h = g/f$  that is statistically indistinguishable from uniform when  $f$  and  $g$  are sampled from  $D_{\sigma}$ . Moreover, they show that using such parameters allows one to remove the NTRU assumption from a proof of the NTRU cryptosystem. The  $\sigma$  needed for statistical security depends on the size of *q* and *d*. This suggests that fixing *q* and *d* and increasing  $\sigma$  makes the NTRU problem harder.

This observation goes some way to answering the first part of our question since it is clear that, for a sufficiently large  $\sigma$ , both SKR and DSD become ineffective.

Whilst using statistically uniform public keys provides peace of mind, this practice comes with significant efficiency losses. In addition to much larger key sizes, conditions for a cryptosystem's correctness can become much more constraining. Note that for correct decryption of the NTRUEncrypt cryptosystem defined in Fig. [2,](#page-8-0) one needs the relation  $||p(gs + fe) + fm||_{∞} < q/2$  to hold. Clearly, using larger secrets *f* and *g* thus leads to less favourable parameters by pushing up the modulus *q*.

We, therefore, have a balancing act that needs to be performed when setting NTRU parameters; to keep parameters small whilst avoiding the attacks affecting overstretched regimes. Fortunately, the script provided in [\[DvW21\]](#page-34-5) also allows for NTRU hardness estimations using any choice of  $\sigma$  though no analysis is performed in their work outside the ternary case. Nevertheless, their estimator provides a tool, much like the LWE estimator of Albrecht et al. [\[APS15\]](#page-31-8), to analyse the concrete hardness of any given NTRU parameter set.

**A More General Fatigue Relation.** In our analysis, we are interested in answering the second part of the above question. In particular, we would like to know by *how much*

<span id="page-23-0"></span><sup>7</sup>See [github.com/WvanWoerden/NTRUFatigue](https://github.com/WvanWoerden/NTRUFatigue) for their code.

<span id="page-23-1"></span> $^8\mbox{Lattice estimator: }$  [github.com/malb/lattice-estimator.](https://github.com/malb/lattice-estimator)

an increase in NTRU secret size affects the position of the fatigue point for a given ring dimension.

A simple calculation, following the analysis of [\[DvW21\]](#page-34-5), Section 3.2, confirms that the asymptotic relation  $q = d^{(2.484 + o(1))}$  holds regardless of the value of  $\sigma$ . This suggests that if the value of  $\sigma$  plays a role in the concrete, average case relation, it manifests in the leading constant. We can thus infer that, for some function  $\psi$  and constant *c*, the fatigue point is given by

$$
q = c \cdot \psi(\sigma) \cdot d^{2.484}.
$$

In order to determine the nature of  $\psi$ , we consider a range of  $\sigma \in [2, 2^2, \ldots, 2^{20}]$ . For each *σ*, we perform a loglog-linear regression on the estimated fatigue points overall prime ring dimensions 199*, . . . ,* 499. This mimics the calculations of [\[DvW21\]](#page-34-5) used in the ternary case. For a full explanation of why this is a sensible range to examine, we refer the reader to Section 5.3 of that work.

Next, we consider the predicted fatigue points as a geometric series. This reveals the predicted average-case fatigue point to be

<span id="page-24-0"></span>
$$
q = 0.0058 \cdot \sigma^2 \cdot d^{2.484}.\tag{3}
$$

The precision of this relation across all  $\sigma$  considered is very high. Whilst we could extend this part of our analysis to larger  $\sigma$ , it is highly unlikely that, for cryptographic applications, one would need to take  $\sigma$  higher than  $2^{20}$ . We note also that, setting  $\sigma^2 = 2/3$ , we recover the fatigue point determined for the ternary case [\[DvW21\]](#page-34-5).

This gives a definitive answer to our question about the impact of  $\sigma$  on the fatigue point. To give more gravity to this prediction, we also run a series of experiments for computable ring dimensions to validate this estimate. The results are displayed in Fig. [7.](#page-25-0)

We also give a second figure (Fig. [8\)](#page-25-1) in which we plot  $q/\sigma^2$  along the vertical axis. This reveals the accuracy of the preceding constant by showing how closely bunched the estimations and experiments are when normalised across varying  $\sigma$ . As Ducas and van Woerden observed in the ternary case, the estimator is slightly pessimistic, predicting a fatigue point roughly 15% lower than the one suggested by actual experiments. They give potential explanations for this discrepancy, pointing to the slope parameter used in the estimator, which is not well calibrated for such small block sizes. In practice, though, this small error only translates to a difference of 2-3 in the block size needed to run BKZ and thus hardly affects the predicted security. Importantly, our experiments show that this error remains constant even at larger moduli.

**The Significance of**  $\sigma^2$ . Having determined the impact of  $\sigma$  on the concrete fatigue point for NTRU, we reflect on the structure of Eq. [\(3\)](#page-24-0). As an illustrating example, let us return to the decryption correctness constraint for the NTRU cryptosystem. This can be written as  $\sigma \cdot \mathcal{F}(p, d, \nu) < q$  for some function F. Suppose for a given parameter set  $(d, q, \sigma)$ , this constraint is satisfied, but the corresponding NTRU instance does not provide adequate security. Let us then increase  $q$  by a constant factor  $\delta$ , say. According to the constraint, this gives room for an increase in  $\sigma$  to  $\delta \cdot \sigma$ . Then Eq. [\(3\)](#page-24-0) tells us that the new fatigue point for the set  $(d, \delta \cdot q, \delta \cdot \sigma)$  increases by a factor of  $\delta^2$ . The important observation here is that, while increasing *q* in the first move might weaken the NTRU instance, the same increase permitted for  $\sigma$  actually gives rise to a *net increase in the hardness of the instance*. In summary, Eq. [\(3\)](#page-24-0) tells us that it is possible to 'win' this cat-and-mouse game for NTRU that so often arises when setting lattice parameters.

We now consider how our analysis might be applied to existing works to refine parameter choices.

<span id="page-25-0"></span>

**Figure 7:** Experimental fatigue point values for a range of  $\sigma$ , calculated using BKZ with 8 tours on matrix NTRU instances. The straight-coloured lines show the estimated values using the (modified) estimator from [\[DvW21\]](#page-34-5).

<span id="page-25-1"></span>

**Figure 8:** Experimental values for  $q/\sigma^2$  illustrate that the fatigue point, when adjusted for  $\sigma$ , is modelled by  $q/\sigma^2 = 0.0058 \cdot d^{2.484}$ .

#### **4.2 Implications for Existing Work**

While the authors of [\[DvW21\]](#page-34-5) note that parameters used in the NTRU-based NIST finalists are still secure to the degrees claimed, many works in the literature use different sets, some of which may fall foul of the dense sublattice attack, and thus, one needs to use the techniques described in the previous section to set parameters.

We examine an existing primitive in which the parameters fall short of providing claimed security levels. However, as suggested by Eq. [\(3\)](#page-24-0), we can carefully re-select parameters so that a small increase in the secrets yields the security bump-up needed.

**Blind Signatures [\[dPK22\]](#page-34-6).** del Pino and Katsumata present a lattice-based (partially) blind signature using trapdoor sampling. In the (round optimal) construction given, a user passes the message to be signed in a *blind* way so that the signer does not learn the message they sign. This is done by committing to the message and then proving the well-formedness of this commitment. We will call this the *first flow*. The signer then creates an output passed back to the user (*second flow*). Finally, the user computes a signature for its original message using this response message from the signer.

In the first flow, Pino and Katsumata employ the NTRU-based linear homomorphic commitment scheme (LinHC) of [\[Kat21\]](#page-35-6) to ensure the soundness and overall Quantum Random Oracle Model (QROM) security of the well-formedness proof. One must, therefore, choose parameters so that the relevant NTRU instance is hard. The choice of  $d = 2048$ ,  $q = 2^{66}$ , and ternary NTRU secrets is informed by the constraint requiring straight-line extractability of the proof system. However, as we have observed, such large moduli run the risk of taking a parameter set into overstretched territory. Moreover, these values give rise to only 63 bits of security when run through the estimator of [\[DvW21\]](#page-34-5) rather than 128.

To rectify this situation, there are two common strategies; either one can increase the ring dimension used throughout the scheme or use sufficiently large NTRU secrets that the corresponding public key is *statistically* indistinguishable from uniform.

Doubling the ring dimension in [\[dPK22\]](#page-34-6) from 2048 to 4096 (to retain the implementation benefits of a power-of-two dimension) and computing the other parameters accordingly, 128 bits of security is reached at the cost of doubling the sign-request flow (69*.*2MB), doubling the returned 'pre-signature', and doubling the user's final signature size to 200 KB.

The alternative method, using a statistically uniform public commitment key turns out to be impossible whilst satisfying all parameter constraints simultaneously.

We now exhibit the benefits of the relation Eq.  $(3)$ , as revealed by our analysis, when applied to the problem of setting NTRU parameters with the same ring dimension  $d = 2048$ , we increase  $\sigma_{\text{NTRU}}$  (secret size). This has the effect of pushing up the modulus needed to facilitate the straight-line extraction condition. The reader might observe that increasing *q* reduces the hardness of the problem again. However, Eq. [\(3\)](#page-24-0) reveals that it is possible to 'win' this cat-and-mouse game since the fatigue point increases *quadratically* with the size of the secrets. We thus propose the following parameters to ensure 128 bit security is reached:

$$
q \approx 2^{74}, \quad p \approx 2^{41}, \quad \sigma_{\text{NTRU}} = 13,
$$

where  $p$  is the prime used to commit to the witness in the LinHC protocol. Fortunately, this change only has a small effect on the total communication cost. In the first flow, the user signing query increases from 34 MB to 35*.*4 MB, and the sizes of the user's pre-signature and final signature output are unchanged. This significantly improves the sizes that arise from changing the ring dimension and avoids doubling the final signature.

**Summary.** Simply increasing the size of the NTRU secrets may be all that is needed to ensure the correct security threshold is reached. In other settings, this also pushes up the modulus over which a scheme is defined, as in the examples above. However, the scheme may also rely on other hardness assumptions, such as RLWE, as in our voting scheme, which is defined over the same ring. Now, the RLWE problem may no longer be hard for the adjusted parameters, and one may need to increase the ring *dimension* to find parameters for which both problems are hard. This can make what was an efficient scheme into one that cannot be deployed in practice.

Clearly, such balancing acts must be approached with a good understanding of the hardness of NTRU instances. We aim to further demonstrate the advantages of this approach when setting concrete parameters for our voting scheme in Section [5](#page-27-0) where our fine-grained analysis allows us to dramatically bring down the overall communication cost.

### <span id="page-27-0"></span>**5 Performance**

We analyse the practical performance of our voting scheme. We begin by identifying all system parameters and any constraints that apply to them. These are displayed in Table [6.](#page-41-0) Next, we compute a sample set of parameters that satisfy the necessary constraints and give rise to a minimum of 128 bits of security. Table [2](#page-28-0) displays these values. Finally, using these parameters, we compute the concrete communication cost of our voting system. The resulting sizes are compared to the previous work of [\[ABGS23\]](#page-31-3), revealing a significant improvement in the state-of-the-art for cryptographic voting from quantum-safe assumptions. These results are displayed in Table [1.](#page-4-0)

#### **5.1 Setting Parameters**

We begin by collecting all parameters of the scheme and noting any constraints applying to them in Table [6.](#page-41-0)

Next, we closely examine the constraint needed for the correct (perfect) decryption of votes as performed by the Comb algorithm. This turns out to be the most influential constraint on the overall efficiency of the scheme. In particular, this constraint informs our choice of the global ring dimension *d* and modulus *q*, which most directly affect the communication sizes.

**Decryption Correctness.** After passing through the mix-net of  $\xi_1$  shuffle servers, a ciphertext is of the form

$$
c = p(h \sum_{k \in [\xi_1]} s_k + \sum_{k \in [\xi_1]} e_k) + m,
$$

where the encryption randomness terms  $s_k$  and  $e_k$  are sampled from  $S_\nu$ . Next, this ciphertext is passed to a decryption server, which computes a decryption share of the form  $ds_j = f_j \cdot c + pE_j$ . Then the Comb algorithm, on collecting  $\{ds_j\}_{j \in [\xi_2]}$ , outputs

$$
v' = (\sum_{j \in [\xi_2]} \mathsf{ds}_j \mod q) \mod p.
$$

In order for the result of this process to yield the original ballot cast, we require the infinity norm of the sum here to be bounded by  $|q/2|$ . It follows that a sufficient constraint for this correct decryption is:

<span id="page-27-1"></span>
$$
p \cdot d \cdot t \cdot \sigma_{\text{NTRU}} \cdot (2\xi_1 \cdot \nu + 1/2)(1 + 2^{\text{sec}}) < \lfloor q/2 \rfloor,\tag{4}
$$

where  $t$  is the rejection parameter in KeyGen $_{\text{NTRU}}$ .

<span id="page-28-0"></span>

Parameter	Explanation	Value
$\lambda$	Computational security parameter	128
$d_{\cdot}$	Ring dimension	2048
q	Ciphertext and commitment modulus	$\approx 2^{59}$
sec	Statistical security parameter	40
$\boldsymbol{p}$	Plaintext modulus	$\overline{2}$
t	$KeyGenNTRU rejection parameter$	1.058
$\nu$	Infinity norm of encryption randomness	1
$\xi_1, \xi_2$	Number of shuffle and decryption servers	$\overline{4}$
$B_{\mathsf{Com}}$	Infinity norm of commitment randomness	$\mathbf{1}$
$B_{\text{Dec}}$	Noise in ciphertext	262144
$B_{\rm Drown}$	Infinity norm of noise drowning term $E_{ij}$	$\approx 2^{55}$
$\sigma$ NTRU	Standard deviation for encryption secret key	7.12
$\eta$	Reed-Solomon encoding randomness length	325
$\ell_{\mathsf{Small}}$	Proof batch size in $\Pi_{\mathsf{Small}}$	9830
$\ell_{\mathsf{Bnd}}$	Proof batch size in $\Pi_{\mathsf{Bnd}}$	12288
$\mu$ Small	Reed-Solomon message length in $\Pi_{\mathsf{Small}}$	10565
$\mu_{\mathsf{Bnd}}$	Reed-Solomon message length in $\Pi_{\text{Bnd}}$	8517
$\mu'_{\mathsf{Small}}$	Reed-Solomon message dimension in $\Pi_{\mathsf{Small}}$	23988
$\mu'_{\mathsf{Bnd}}$	Reed-Solomon message dimension in $\Pi_{\text{Bnd}}$	181550
$\gamma$ Small	Reed-Solomon code length in $\Pi_{\mathsf{Small}}$	26616
$\gamma$ Bnd	Reed-Solomon code length in $\Pi_{\text{Bnd}}$	198668

**Table 2:** Sample parameter set.

**Computational Security.** Having chosen parameters satisfying the constraints of Table [6,](#page-41-0) we must ensure that the underpinning lattice problems are sufficiently hard for these parameters.

For RLWE we follow standard convention by using the estimator [\[APS15\]](#page-31-8). This estimates the cost of BKZ conservatively by focusing only on the cost of a single uSVP oracle call, a core operation in BKZ. The number of such calls required has been estimated to be 8*d* for a lattice dimension *d*, and we follow this estimate.

To determine the NTRU problem's hardness, we use the analysis of Section [4.](#page-21-0) Having settled on a ring dimension *d* and modulus *q* giving sufficient hardness of the RLWE problem, we use [\(4\)](#page-27-1) to determine the maximum standard deviation permissible for generating the NTRU secrets  $(f, g)$ . Finally, following the procedure described in Section [4,](#page-21-0) we calculate the estimated hardness of NTRU. Again, we employ the conservative formula  $0.292\beta + 16.4 + \log_2(8d)$  used in [\[DTGW17,](#page-34-9) [SPL](#page-37-10)<sup>+</sup>17, [BIP](#page-32-7)<sup>+</sup>22] to compute bit-security from blocksize *β*.

In order to ensure the binding property of the BDLOP commitment schemes we use,

Scheme	$c_i$	$\llbracket R_q \rrbracket$	$\pi$ Shuf	$\pi_{\mathsf{Lin}}$	$\pi$ Small	$\pi$ Bnd
[ABGS23] [KB]	80	80/120	150	35	20	
Our [KB]		30	63	18	22	22

<span id="page-29-0"></span>**Table 3:** Ciphertext, commitment, and proof sizes per voter. Note that the two sizes in [\[ABGS23\]](#page-31-3) reflect commitments to noise-drowning terms and ciphertexts, respectively.

<span id="page-29-1"></span>**Table 4:** Ciphertext and commitment timings. Numbers were obtained averaging over  $10^4$ executions measured using the cycle counter available on the platform.

Scheme	Com	Open	Enc	<b>Dec</b>	<b>DDec</b>
$[{\rm ABGS23}]$ [ms]	0.45	2.76	0.74	0.64	1.56
Our $[ms]$	0.17	0.80	0.20	0.21	0.45

the RSIS problem must be hard. We use the relation due to Micciancio and Regev [\[MR09\]](#page-36-10), which states that LLL will recover a short vector a vector of 2-norm  $2^{(2\sqrt{d\log_2 q \log_2 \delta})}$ . *δ* is the root Hermite factor and *δ <* 1*.*0045 gives rise to at least 128 bits of security. Owing to the horizontally long nature of the commitment matrix used, the hardness of the corresponding RSIS instance easily meets this threshold.

#### <span id="page-29-2"></span>**5.2 Sample Parameters and Total Size**

Table [2](#page-28-0) gives a sample set of parameters generated by following the process described in the previous section. In Table [3,](#page-29-0) we present the total sizes of objects in our voting scheme and compare them with those of [\[ABGS23\]](#page-31-3). We denote the output of each shuffle node by  $\pi_{\mathcal{S}_i}$ , including ciphertexts, commitments, proofs of shortness, and shuffle proofs. Similarly, we denote the total output of each decryption node as  $\pi_{\mathcal{D}_j}$ , consisting of decryption shares, commitments, proofs of linearity and boundedness.

Our scheme reduces ciphertext size by over a factor of five. Moreover, the reduction in commitment sizes and constituent proofs leads to shuffle server outputs of 130 KB per vote, which are three times smaller, and decryption server outputs of 85 KB per vote, which are half of those in [\[ABGS23\]](#page-31-3). This represents a 2*.*5× overall efficiency gain over [\[ABGS23\]](#page-31-3) as summarised in Table [1.](#page-4-0)

#### **5.3 Benchmarks**

We adapt the proof-of-concept implementation by [\[ABGS23\]](#page-31-3) to fit our scheme since the framework is the same. Our benchmarks were collected on an Intel Kaby Lake Core i7-7700 CPU machine with 64 GB of RAM running single-threaded at 3*.*6 GHz, with Turbo Boost disabled to reduce measurement variability. This is a similar machine as in [\[ABGS23\]](#page-31-3). Our code is available at [https://github.com/carrosa/ntru\\_voting\\_impl](https://github.com/carrosa/ntru_voting_impl).

We compare the timings in Table [4](#page-29-1) and Table [5.](#page-30-0) Analysing our experiments, each shuffle server takes  $(0.20 + 0.17 + 17.5 + 44.2) = 62$  ms and each decryption server takes  $(0.17 + 0.45 + 16.9 + 310.5) = 328$  ms. Given four servers, where shuffles are performed sequentially and decryption is performed in parallel, the total time is 576 ms, making our scheme twice as fast as [\[ABGS23\]](#page-31-3) as summarized in Table [1.](#page-4-0)

We finally note that the proofs of linearity in the shuffle and the batched proofs of shortness and boundedness during shuffles and decryption can be computed in parallel,

Scheme	$\pi_{\mathsf{Lin}}$	$\pi$ Shuf	$\pi$ Small	$\pi$ <sub>Bnd</sub>	
$[ABGS23]$ [ms]	$(43.4+6.4)$	$(44.9 + 7.9)$	$(214.4 + 10.0)$	$(92.7 + 23.9)$	
$Our$ [ms]	$(16.9 + 2.0)$	$(17.5 + 2.1)$	$(44.2 + 4.0)$	$(310.5 + 4.3)$	

<span id="page-30-0"></span>**Table 5:** Proving and verification times, obtained by computing the average of 100 executions with  $\tau = 1000$ .

and that powerful servers dedicated to an election with Turbo Boost enabled would most likely outperform our numbers by at least an order of magnitude.

#### **5.4 Future Improvements**

We provide some directions for interesting future work:

- 1. *Return codes.* To extend our scheme and ensure voter verifiability, we need to add return codes to our scheme. This can be done by extending the work of [\[HS22\]](#page-34-10) from BGV to NTRU. This also includes verifiable encryption [\[LNP22\]](#page-35-5).
- 2. *Improved noise analysis.* Our results can possibly be improved using techniques in [\[AKSY22,](#page-31-9) [BS23b,](#page-33-8) [CSS](#page-33-9)<sup>+</sup>22, [KLSS23\]](#page-35-7). We use 40 bits of statistical noise drowning to protect the secret key in the distributed decryption protocol. This can possibly be improved if we choose parameters based on how many ciphertexts we will decrypt or change noise drowning techniques to be Gaussian distributed, compute the Rényi divergence, or analyse hints to estimate the leakage.
- 3. *Module assumptions.* The new NIST post-quantum key-encapsulation mechanism  $ML-KEM$  [\[SAB](#page-37-0)<sup>+</sup>22] and digital signature ML-DSA [\[LDK](#page-35-0)<sup>+</sup>22] are based on the module LWE and SIS problems [\[LS15\]](#page-36-3). Our scheme could potentially be improved by instantiating our framework based on these assumptions combined with the more recent module NTRU assumption [\[CKKS19,](#page-33-6) [CPS](#page-33-7)<sup>+</sup>20].
- 4. *Succing lattice ZKPs.* Recent development of succinct proof systems from lattice assumptions such as LaBRADOR [\[BS23a\]](#page-33-10) (which can be made zero-knowledge) could be applied to the shuffle and decryption processes in our scheme to produce sub-linear proof sizes (the overall communication would stay linear since we need to send commitments, ciphertexts and decryption shares for each vote).
- 5. *Improved parameters in other schemes.* Our extended NTRU analysis might lead to more efficient FHE parameters in [\[BIP](#page-32-7)<sup>+</sup>22] and [\[Klu22\]](#page-35-8) using the same methodology that led to a more efficient instantiation of NTRUEncrypt .

### <span id="page-39-0"></span>**A Security of Verifiable Mixing**

We define *completeness*, *soundness* and *simulatability* for a mixing protocol  $\Pi_{\text{Mix}}$  executed by a prover Prover, with respect to a generic encryption scheme  $\mathcal{E} =$  (KeyGen, Enc, Dec) [\[ABGS23\]](#page-31-3).

**Definition 5** (Mixing Completeness). We say that the mixing protocol  $\Pi_{Mix}$  is *complete* if for honest PPT parties Prover and Verifier that follows the protocol then Prover on input a set of honestly generated ciphertexts will output a new set of ciphertexts together with a proof such that Verifier accepts the proof and the output ciphertexts decrypt to the same set of messages as the input ciphertexts. Hence, we want that for all  $(pp, pk, sk) \leftarrow \text{KeyGen}(1^{\kappa}),$  ${c_i}_{i\in[\tau]}\leftarrow \mathsf{Enc}(\mathsf{pk}, \{m_i\}_{i\in[\tau]})$ , and  $(\{\hat{c}_i\}_{i\in[\tau]}, \pi) \leftarrow \mathsf{Prover}(\mathsf{pp}, \mathsf{pk}, \{c_i\}_{i\in[\tau]})$ , we have

$$
\Pr\biggl[\inf_{1 \leftarrow \text{Verifier}(\textsf{pp},\, \textsf{pk},\, \{c_i\}_{i \in [\tau]},\, \{\hat{c}_i\}_{i \in [\tau]}, \pi)\biggr] \leq 1 - \epsilon(\lambda),
$$

where the probability is taken over KeyGen, Enc and Prover.

**Definition 6** (Mixing Soundness). We say that the mixing protocol  $\Pi_{\text{Mix}}$  is *sound* if a dishonest PPT adversary Adv that can behave arbitrarily on input a set of honestly generated ciphertexts will not be able to output a new set of ciphertexts together with a proof such that an honest Verifier accepts the proof but the output ciphertexts decrypt to a different set of messages than the input ciphertexts. Hence, we want that for all  $(pp, pk, sk) \leftarrow \text{KeyGen}(1^{\kappa}),$  ${c_i}_{i\in[\tau]}\leftarrow \mathsf{Enc}(\mathsf{pk}, \{m_i\}_{i\in[\tau]})$ , and  $(\{\hat{c}_i\}_{i\in[\tau]}, \pi) \leftarrow \mathsf{Adv}(\mathsf{pp}, \mathsf{pk}, \{c_i\}_{i\in[\tau]})$ , we have

$$
\Pr\bigg[1 \leftarrow \text{Verifier}(pp, pk, \{c_i\}_{i \in [\tau]}, \{\hat{c}_i\}_{i \in [\tau]}, \pi)\bigg] \leq \epsilon(\lambda),
$$

where the probability is taken over KeyGen, Enc and Adv.

**Definition 7** (Mixing Simulatability). We say that the mixing protocol  $\Pi_{Mix}$  is *simulatable* if a PPT adversary A that on input a set of honestly generated ciphertexts can not distinguish between a real execution of the mixing protocol with accepting output and a protocol execution from a PPT simulator  $\mathcal S$  (given a set honestly mixed output ciphertexts) producing a simulated mixing proof. Hence, we want that

$$
\left|\Pr\left[b=b': \begin{pmatrix} (\mathsf{pp},\mathsf{pk},\mathsf{sk}) \leftarrow \mathsf{KeyGen}(1^{\kappa}); b \stackrel{\ast}{\leftarrow} \{0,1\} \\ \{c_i\}_{i\in[\tau]}\leftarrow \mathsf{Enc}(\mathsf{pk},\{m_i\}_{i\in[\tau]}) \\ (\{\hat{c}_i\}_{i\in[\tau]},\pi^{(0)}) \leftarrow \mathsf{Prover}(\mathsf{pp},\mathsf{pk},\{c_i\}_{i\in[\tau]}) \\ (\pi^{(1)}) \leftarrow \mathcal{S}(\mathsf{pp},\mathsf{pk},\{c_i\}_{i\in[\tau]},\{\hat{c}_i\}_{i\in[\tau]}) \\ b' \leftarrow \mathsf{Adv}(\mathsf{pp},\mathsf{pk},\{c_i\}_{i\in[\tau]},\{\hat{c}_i\}_{i\in[\tau]},\pi^{(b)}) \end{pmatrix} - \frac{1}{2}\right| \leq \epsilon(\lambda),
$$

where the probability is taken over KeyGen, Enc, Prover,  $S$  and Adv.

### <span id="page-39-1"></span>**B Security of Distributed Decryption**

Here we define the syntax and security properties for a PKE with distributed decryption [\[ABGS23\]](#page-31-3).

**Definition 8** (PKE with Distributed Decryption)**.** A PKE scheme with distributed decryption consists of five algorithms: key generation (KeyGen), encryption (Enc), decryption (Dec), distributed decryption (DDec), and combine (Comb), where

KeyGen. On input security parameter  $1^{\lambda}$  and number of key-shares  $\xi_2$ , outputs public parameters pp, a public key pk, a secret key sk, and key-shares  $\{sk_j\}$ ,

- Enc. On input pk and messages  $\{m_i\}$ , outputs ciphertexts  $\{c_i\}$ ,
- Dec. On input sk and ciphertexts  $\{c_i\}$ , outputs messages  $\{m_i\}$ ,
- DDec. On input a secret key share  $sk_{j*}$  and ciphertexts  $\{c_i\}$ , outputs decryption shares  ${ds_{i,j*}}$ ,
- Comb. On input ciphertexts  ${c_i}$  and decryption shares  ${ds_{i,j}}$ , outputs either messages  $\{m_i\}$  or  $\perp$ ,

and pp are implicit inputs to Enc, Dec, DDec and Comb.

**Definition 9** (Chosen Plaintext Security). We say that the public key encryption scheme is secure against *chosen plaintext attacks* if an adversary Adv, after choosing two messages  $m_0$  and  $m_1$  and receiving an encryption *c* of either  $m_0$  or  $m_1$  (chosen at random), cannot distinguish which message *c* is an encryption of. Hence, we want that

$$
\left|\Pr\left[b=b' \ : \begin{array}{l} (\mathsf{pp},\mathsf{pk},\mathsf{sk}) \leftarrow \mathsf{KeyGen}(1^\kappa) \\ (m_0,m_1,\mathsf{st}) \leftarrow \mathsf{Adv}(\mathsf{pp},\mathsf{pk}) \\ b \stackrel{\$}{{\leftarrow}} \{0,1\}, c \leftarrow \mathsf{Enc}(\mathsf{pk},m_b) \\ b' \leftarrow \mathsf{Adv}(c,\mathsf{st}) \end{array}\right]-\frac{1}{2}\right| \leq \epsilon(\lambda),\right.
$$

where the probability is taken over KeyGen and Enc.

**Definition 10** (Threshold Correctness)**.** We say that the public key distributed encryption scheme is *threshold correct* with respect to  $P_{sk}(\cdot)$  if the following probability equals 1:

$$
\Pr\left[\begin{matrix}\textsf{Comb}(\{c_i\}_{i\in[\tau]},\{\textsf{ds}_{i,j}\}_{j\in[\tau]}^{j\in[\xi_2]}) & (\textsf{pp},\textsf{pk},\textsf{sk},\{\textsf{sk}_j\}_{j\in[\xi_2]}) \leftarrow \textsf{KeyGen}(1^\lambda,\xi_2) \\ = & \{c_1,\ldots,c_\tau\} \leftarrow \mathcal{A}(\textsf{pp},\textsf{pk}) \\ = & \forall i \in [\tau]:\ P_{\textsf{sk}}(c_i) = 1, \forall j \in [\xi_2]: \\ \{\textsf{ds}_{i,j}\}_{i\in[\tau]} \leftarrow \textsf{DDec}(\textsf{sk}_j,\{c_i\}_{i\in[\tau]})\end{matrix}\right],
$$

where the probability is taken over KeyGen and DDec.

**Definition 11** (Threshold Verifiability)**.** A PKE scheme with distributed decryption is *threshold verifiable* with respect to  $P_{\text{sk}}(\cdot)$  if an adversary A corrupting  $J \subseteq [\xi_2]$  secret key shares  $\{sk_j\}_{j\in J}$  cannot convince Comb to accept maliciously created decryption shares  ${\{\mathsf{ds}}_{i,j}\}_{i \in [\tau], j \in J}$ . More concretely, the following probability is bounded by a negligible  $\epsilon(\lambda)$ :

$$
\Pr\left[\begin{matrix}\text{Dec}(\text{sk},\{c_i\}_{i\in[\tau]})&(\text{pp},\text{pk},\text{sk},\{\text{sk}_j\}_{j\in[\xi_2]})\leftarrow\text{KeyGen}(1^\lambda,\xi_2)\\ \neq&(\{c_1,\ldots,c_\tau\})\leftarrow\mathcal{A}(\text{pp},\text{pk},\{\text{sk}_j\}_{j\in J})\\ \text{Comb}(\{c_i\}_{i\in[\tau]},\{\text{ds}_{i,j}\}_{i\in[\tau]}^{\leq[\xi_2]}) : \begin{array}{c}(\{c_1,\ldots,c_\tau\})\leftarrow\mathcal{A}(\text{pp},\text{pk},\{\text{sk}_j\}_{j\in J})\\ \forall i\in[\tau]:\ P_{\text{sk}}(c_i)=1,\forall j\not\in J:\\ \{\text{ds}_{i,j}\}_{i\in[\tau],j\in J}\leftarrow\mathcal{A}(\{\text{ds}_{i,j}\}_{i\in[\tau],j\not\in J})\end{array}\right],
$$

where the probability is taken over KeyGen and DDec.

**Definition 12** (Distributed Decryption Simulatability)**.** A PKE scheme with distributed decryption is *simulatable* with respect to  $P_{\rm sk}(\cdot)$  if an adversary A corrupting  $J \subsetneq [\xi_2]$  secret key shares  $\{sk_j\}_{j\in J}$  cannot distinguish the transcript of the decryption protocol from a simulation by a simulator Sim which only gets  $\{sk_j\}_{j\in J}$  as well as correct decryptions as input. More concretely, the following probability is bounded by a negligible  $\epsilon$ (sec):

$$
\left|\Pr\left[\begin{matrix}(\text{pp},\text{pk},\text{sk},\{\text{sk}\}_{j\in[\xi_2]})\leftarrow\text{KeyGen}(1^\lambda,\xi_2)\\(\{c_1,\ldots,c_\tau\})\leftarrow\mathcal{A}(\text{pp},\text{pk},\{\text{sk}_j\}_{j\in J})\\ \forall i\in[\tau]:\ P_{\text{sk}}(c_i)=1\\ \{\text{ds}_{i,j}^0\}\leftarrow\text{DDec}(\{\text{sk}_j\}_{j\in[\xi_2]},\{c_i\}_{i\in[\tau]})\\ \{\text{ds}_{i,j}^1\}\leftarrow\text{Sim}(\text{pp},\{\text{sk}_j\}_{j\in J},\{c_i,\text{Dec}(\text{sk},c_i)\}_{i\in[\tau]})\\ b\stackrel{\text{ss}}{\leftarrow}\{0,1\},b'\leftarrow\mathcal{A}(\{\text{ds}_{i,j}^b\}_{i\in[\tau],j\in[\xi_2]})\end{matrix}\right)\right|-\frac{1}{2}\right|,
$$

where the probability is taken over KeyGen*,* DDec*,* Sim.

## **C Parameter Constraints**

Here we describe the parameters used in our electronic voting scheme. Table [6](#page-41-0) lists these and makes explicit any constraints that apply to them. These constraints inform the choice of concrete values computed in Section [5.2.](#page-29-2)

<span id="page-41-0"></span>

Parameter	Explanation	Constraints	
$\lambda$	Computational security parameter	$\geq 128$	
sec	Statistical security parameter	$\geq 40$	
$\boldsymbol{d}$	Ring dimension of $R_p$ and $R_q$	$d$ a power of two	
$\boldsymbol{p}$	Plaintext modulus	$p$ a small prime	
q	Ciphertext and commitment modulus	Prime $q=1 \mod 2d$ s.t. $\left\  \sum_{j \in \xi_2} \textsf{ds}_j \right\ _\infty \leq \lfloor q/2 \rfloor$	
$\bar{t}$	KeyGen <sub>NTRU</sub> rejection parameter	Set for rej. prob. $\langle 1/1000$ (Lemma 1)	
$\boldsymbol{k}$	Length of binding vector in BDLOP commitment	k > 2	
$\mathcal{C}$	Challenge space for linear ZK proofs of commitments	$\mathcal{C}=\{c\in R_q\mid \left\Vert c\right\Vert _{\infty}=1, \left\Vert c\right\Vert _{1}=\kappa\}$	
$\kappa$	Maximum $\ell_1$ -norm of elements in $\mathcal C$	$2^{\kappa} \cdot {d \choose \kappa} > 2^{\lambda}$	
$\xi_1, \xi_2$	Number of shuffle and decryption-servers	At least two servers	
$B_{\mathsf{Com}}$	Bound on the commitment noise	So that SIS is hard	
$B_{\rm Dec}$	Noise in ciphertext	$B_{\mathsf{Dec}} = p \cdot d \cdot t \cdot \sigma_{\mathsf{NTRU}} \cdot \left(2 \xi_1 \cdot \nu + 1/2 \right)$	
$B_{\text{Drown}}$	Infinity norm of noise drowning term $E_{ij}$	$B_{\text{Drown}} = 2^{\text{sec}}(B_{\text{Dec}}/p\xi_2)$	
$\sigma$ NTRU	Standard deviation for encryption secret key	So that NTRU is hard	
$\nu$	Bound on encryption randomness	So that LWE is hard	
$\sigma_{\mathsf{Com}}$	Standard deviation in ZK proofs of linear relations	Chosen to be $\sigma_{\mathsf{Com}} = \kappa \cdot B_{\mathsf{Com}} \cdot \sqrt{kd}$	
$\tau$	Total number of messages/number of voters	For soundness we need $(\tau^{\delta}+1)/ R_q <2^{-\lambda}$	
$\eta$	Reed-Solomon encoding randomness length	Make soundness $\geq 2^{-\lambda}$ in $\Pi_{\mathsf{Small}}$ and $\Pi_{\mathsf{Bnd}}$	
$\ell_{\sf Small}$	Proof batch size in $\Pi_{\mathsf{Small}}$	Same secret length as in [ABGS23]	
$\ell_{\mathsf{Bnd}}$	Proof batch size in $\Pi_{\mathsf{Bnd}}$	Same secret length as in [ABGS23]	
$\mu$ Small	Reed-Solomon message length in $\Pi_{\mathsf{Small}}$	$\mu_{\text{Small}} = (k+2) \cdot d + \eta$	
$\mu$ Bnd	Reed-Solomon message length in $\Pi_{\mathsf{Bnd}}$	$\mu_{\text{Bnd}} = (k+1) \cdot d + \eta$	
$\mu'_{\sf Small}$	Reed-Solomon message dimension in $\Pi_{\mathsf{Small}}$	$\mu_{\mathsf{Small}} \leq \mu'_{\mathsf{Small}} \leq \gamma < q$	
$\mu'_{\text{Bnd}}$	Reed-Solomon message dimension in $\Pi_{\mathsf{Small}}$	$\mu_{\mathsf{Bnd}} \leq \mu'_{\mathsf{Bnd}} \leq \gamma < q$	
$\gamma$ Small	Reed-Solomon code length in $\Pi_{\text{Bnd}}$	$\mu_{\mathsf{Small}} \leq \mu'_{\mathsf{Small}} \leq \gamma < q$	
$\gamma$ Bnd	Reed-Solomon code length in $\Pi_{\text{Bnd}}$	$\mu_{\mathsf{Bnd}} \leq \mu'_{\mathsf{Bnd}} \leq \gamma < q$	

**Table 6:** System parameters and constraints.
