Abstract. This work presents SPHINCSLET, the first fully standard-compliant and area-efficient hardware implementation of the SLH-DSA algorithm, formerly known as SPHINCS+, a post-quantum digital signature scheme. SPHINCSLET is designed to be parameterizable across different security levels and hash functions, offering a balanced trade-off between area efficiency and performance. Existing hardware implementations either feature a large area footprint to achieve fast signing and verification or adopt a coprocessor-based approach that significantly slows down these operations. SPHINCSLET addresses this gap by delivering a $4.7 \times$ reduction in area compared to high-speed designs while achieving a $2.5 \times$ to $5 \times$ improvement in signing time over the most efficient coprocessor-based designs for a SHAKE256-based SPHINCS+ implementation. The SHAKE256-based SPHINCS+ FPGA implementation targeting the AMD Artix-7 requires fewer than 10.8K LUTs for any security level of SLH-DSA. Furthermore, the SHA-2-based SPHINCS+ implementation achieves a $2 \times$ to $4 \times$ speedup in signature generation across various security levels compared to existing SLH-DSA hardware, all while maintaining a compact area footprint of 6K to 15K LUTs. This makes it the fastest SHA-2-based SLH-DSA implementation to date. With an optimized balance of area and performance, SPHINCSLET can assist resource-constrained devices in transitioning to post-quantum cryptography.

Keywords: Post-Quantum Cryptography · PQC · Digital Signature Scheme · SPHINCS+ · SLH-DSA

1 Introduction

The advent of practical quantum computers can pose a serious threat to the current public-key cryptographic standards we use [GE21]. As a result, there is an essential need to find alternative means of securing our sensitive information, and this is where post-quantum cryptography (PQC) has emerged as a promising alternative [KP20, Rah22, SM19]. In this context, the National Institute of Standards and Technology (NIST) has started a standardization effort for PQC algorithms [CSD17] in 2016. The process involved the evaluation of different Key Encapsulation Mechanism (KEM) schemes and Digital Signature schemes.

In 2022, after the third round of evaluation, one KEM scheme and three digital signature schemes were selected for standardization $[AAC^+22]$. And among these three digital signature schemes, SPHINCS+ is one of the selected candidates. In August 2024, NIST formally published the final standard (FIPS 205) for the SPHINCS+, the Stateless Hash-Based Digital Signature Algorithm (called SLH-DSA in the standard) [oST23]. Additionally, a new first round started in July 2023 for additional digital signature candidates.

As the name SLH-DSA suggests, SPHINCS+ is a stateless hash-based signature. The stateless classification of SPHINCS+ is sub-divided into the following mechanism:

- 1. The private key used for signing includes several states, and during the signing operation, any state could be chosen at random. Ergo, choosing a specific state over the other states is highly unlikely.
- 2. However, even if the choice of states is repeated, the overall signature scheme is still secure.

As recommended in the standard, SLH-DSA comes in three different security levels (128, 192, and 256), and each security level is sub-divided into two variants: a small signature ('s') variant for smaller signature size and a fast signature ('f') variant where the signature generation is relatively faster. The heart of all the variants lies in the underlying hash function used. Each variant of SLH-DSA could be constructed using either the SHA-2 or the SHAKE256 hash functions.

Among other criteria, hardware evaluation of the PQC candidates was also an essential criterion in the NIST's PQC standardization effort. Therefore, various efforts have been made to develop efficient implementations of SPHINCS+. These works can be categorized mainly into two types: hardware-software (HW-SW) codesign and full hardware (HW) design.

Multiple works in the literature present implementations that are based on a HW-SW codesign such as RISC-V interfaced with a hardware hash accelerator [WOS22, Saa24, KSS24]. These implementations showcase the modularity of the designs, where users can adapt to different hardware hash modules as per their performance requirements. These works also highlight that the area and memory utilization of different security levels remain the same. This is because the processor controls the operational flow of the algorithm.

In addition to this, there are other works that are finite state machine (FSM) based full HW designs dedicated to accelerating SPHINCS+ [ALCZ20, ACZ18, BUG⁺21] signing. While these designs offer compile-time parameterizability to switch between different security levels, the FSM is optimized to work with a specific hash function (e.g., SHAKE256), making it hard to switch to different hash configurations that SPHINCS+ specification [BDE⁺17] proposes.

Our work integrates the most effective design approaches from existing literature to achieve an optimized SPHINCS+ hardware implementation, which we refer to as SPHINCSLET. The proposed design is a low-area, FSM-based, fully hardware architecture that adheres to the FIPS 205 standard¹ for the stateless hash-based digital signature algorithm (SLH-DSA) [oST23] and is compile-time parameterizable across different security levels and hash functions. A key aspect of this design is the HASH_TILE approach, where the finite state machine (FSM) interfaces with a modular HASH_TILE block. The HASH_TILE is a versatile hash module capable of supporting all hash modes required by SLH-DSA. Moreover, the underlying hash function can be easily swapped, allowing flexibility in algorithm selection. The presented evaluation includes implementations for SHAKE256 and SHA-2, as recommended by the standard.

While the fully hardware-based designs in [ALCZ20] achieve high performance, they come at the cost of substantial area overhead. Conversely, the hardware-software co-design approach in [Saa24] reduces area utilization but results in significantly slower performance. The proposed design strikes a balance between these two approaches, offering an optimized trade-off between area and speed. The SHAKE256-based implementation presented in this work is considerably more area-efficient than existing full hardware designs while

¹Our hardware design is compliant with the FIPS 205 version released in Aug 2024.

maintaining high performance. Furthermore, it achieves a $2.5 \times \text{to } 5 \times \text{speedup}$ in signature generation and a $2.3 \times \text{to } 3.5 \times \text{speedup}$ in signature verification across various parameter sets compared to [Saa24], with only a marginal increase in area. Additionally, this work presents the fastest SHA-2-based SPHINCS+ hardware implementation to date.

2 Contribution

Following is the list of contributions to this work:

- We present the fully standard-compliant, lightweight, SLH-DSA hardware implementation that uses SHAKE256 and SHA-2 (SHA256 and SHA512) as the hash functions for its construction. The design is parameterizable at compile time between different security levels and small and fast variants.
- We present a novel HASH_TILE module that is constructed using two hash modules to accomplish different hashing requirements of SLH-DSA. Our HASH_TILE module is parameterizable in terms of different hash functions (SHA256, SHA512, and SHAKE256).
- We present a high-speed full-width implementation of SHAKE256 module.
- We present a detailed evaluation of the related work and compare our work with other outdated SPHINCS+ hardware implementations.
- All the presented results could be regenerated using our code. Our code will be available with the open-source license at https://github.com/caslab-code/pqc-hw-sphincslet.

3 Background

SLH-DSA utilizes several signature schemes as building blocks: Winternitz One-Time Signature Plus (WOTS⁺), Forest of Random Subsets (FORS), and the eXtended Merkle Signature Scheme (XMSS). This section provides a brief introduction to these elements and explains the parameters of SLH-DSA for a better understanding of the SLH-DSA signature scheme.

3.1 SLH-DSA Parameter Sets

Table 1 shows the parameter sets of SLH-DSA in the standard, with each parameter defined as follows: n is the security parameter, length of the private key, public key, or signature element in bytes, h is the height of the SLH-DSA hypertree, d is the number of layers in the SLH-DSA hypertree, logt is the number of leaves per hash tree in FORS, k is the number of hash trees in FORS, w is the Winternitz parameter and len is the number of secret values in the WOTS⁺ private key. Each parameter set can be instantiated using either SHAKE256 or SHA-2 (SHA256 and SHA512) as the underlying hash function.

3.2 Winternitz One-Time Signature Plus

WOTS⁺ is a one-time signature scheme used in SLH-DSA. Generating the WOTS⁺ public key involves creating *len* secret key values, determined by n and w. As shown on line 12 of Algorithm 1, the **PRF** hash function generates each secret value by taking **PK**.seed, **ADRS**, and **SK**.seed as inputs. The public key is obtained through the iterative application of the hash function **F** to the secret keys for w - 1 iterations, known as the *chain* function, as shown on line 14 of Algorithm 1 and Algorithm 2. When it sets i = 0,

Algorithm 1 wots sign, Signature Generation of WOTS⁺

Input: Input Message M, secret seed SK.seed, public seed PK.seed, address ADRS)
Output: WOTS⁺ signature sig
1: csum = 0

2: $msg = base_2^b(M, lg_w, len_1)$ 3: for i = 0 to $len_1 - 1$ do csum = csum + w - 1 - msg[i]4: 5: $csum = csum \ll ((8 - ((len_2 \cdot lg_w) \mod 8)) \mod 8)$ 6: $msg = mgs \parallel base_2^b \left(toByte \left(csum, \left\lceil \frac{len_2 \cdot lg_w}{8} \right\rceil \right), lg_w, len_2 \right)$ 7: skADRS = ADRS8: *skADRS.setTypeAndClear(WOTS PRF)* 9: skADRS.setKeyPairAddress(ADRS.getKeyPairAddress()) 10: for i = 0 to $len_1 - 1$ do skADRS.setChainAddress(i)11: 12: $sk = \mathbf{PRF}(\mathbf{PK}.seed, \mathbf{SK}.seed, skADRS) // Compute \mathbf{PRF}$ hash function ADRS.setChainAddress(i) 13: $sig = chain(sk, 0, msg, \mathbf{PK}.seed, skADRS)$ // Compute chain operation of WOTS⁺ 14:return sig

the iteration number of the hash function \mathbf{F} sets to s = w - 1. After computing *len* public values, they are compressed into a single *n*-byte value using a tweakable hash function. WOTS⁺ is utilized as *wots_sign* with the XMSS Merkle tree as shown in Algorithm 3. The *wots_sign* function combines the hash function **PRF** and the *chain* function at each chain *i* in the range of 0 < i < len - 1.

3.3 eXtended Merkle Signature Scheme (XMSS)

The eXtended Merkle Signature Scheme (XMSS) is one of the key building blocks of the SLH-DSA. Algorithm 3 shows the signature generation of XMSS with use of WOTS⁺, this algorithm represents the ht_sign operation, which is used on line 16 of Algorithm 4 (the top-level SLH-DSA signature generation algorithm). The ht_sign includes the signature generation of XMSS and the computation of the public key from the signature. XMSS utilizes a Merkle tree structure that stores the WOTS⁺ public keys as leaf nodes. This tree is formed by hashing child nodes to generate parent nodes, ending at the root node. A leaf node is selected for WOTS⁺ signature generation. To reduce the chance of choosing the same leaf node repeatedly, SLH-DSA employs d layers of trees, referred to as the hypertree. In the bottom layer, the WOTS⁺ leaf node signs the FORS public key, while in upper layers, the leaf node signs the lower tree's root node for the XMSS.

Algorithm 2 chain, Chain operation of WOTS⁺

Input: Input string X, Index i, no. of steps s, public seed PK.seed, address ADRS) Output: Value of F iterated s times on X 1: if $(i + s) \ge w$ then 2: return NULL 3: tmp = X4: for j = i to i + s - 1 do 5: ADRS.setHashAddress(j) 6: $tmp = \mathbf{F}(\mathbf{PK}.seed, \mathbf{ADRS}, tmp)$ Compute F in chain operation of WOTS⁺ return tmp

Algorithm 3 ht_sign, Signature Generation of XMSS with WOTS⁺

Input: n-byte message M, secret seed SK.seed, index idx, public seed PK.seed, address ADRS)

Output: Signature SIG_{XMSS}

1: for j = 0 to h' - 1 do

2: $k = \lfloor i dx/2^j \rfloor \oplus 1$

```
3: AUTH[j] = xmss\_node(SK.seed, k, j, PK.seed, ADRS) // Compute XMSS trees
```

```
4: ADRS.setTypeAndClear(WOTS_HASH)
```

5: **ADRS**.setKeyPairAddress(idx)

6: sig = wots_sign(M, SK.seed, PK.seed, ADRS) // Compute WOTS+

```
7: SIG_{XMSS} = sig \parallel AUTH
```

return SIG_{XMSS}

3.4 Forest of Random Subsets (FORS)

FORS is referenced on line 12 and 14 of Algorithm 4. In line 12 of Algorithm 4, FORS is utilized at the lowest layer and comprises k Merkle trees, with leaf nodes generated through the hashing of FORS secret keys. In line 14 of Algorithm 4, the k tree root nodes are compressed into a single n-byte valued node, forming the FORS public key.

3.5 Complete SLH-DSA

From SLH-DSA, we implement signature generation and signature verification, the algorithms for which are specified in FIPS 205 [oST23]. These algorithms build on the prior SPHINCS+ [BDE⁺17] submission. We expect key generation to be less frequent, and it can be implemented on standard CPUs, thus we do not provide custom hardware design for it. Key generation mainly computes random bit generator and XMSS tree to generate an SLH-DSA key pair (PK, SK). During the signature generation and verification, SLH-DSA scheme uses six different functions, namely \mathbf{PRF}_{msg} , \mathbf{H}_{msg} , \mathbf{PRF} , \mathbf{T}_{ℓ} , \mathbf{PRF} , and \mathbf{F} from [oST23, Section 4]. Each of these functions utilizes the designated hash function (SHAKE256 or SHA256 or SHA512) for the SLH-DSA instantiations.

3.5.1 Signature Generation

As shown in Algorithm 4, the complete signature generation procedure combines the WOTS⁺, XMSS and FORS schemes (from Section 3.2, Section 3.3, Section 3.4) for quantum resilience. FORS is used to sign the message digest, creating a hypertree structure for the FORS public key to produce an SLH-DSA signature. Extracted bits from the message digest are utilized for signing with the FORS key, selecting an XMSS tree, and choosing a WOTS⁺ key alongside its corresponding FORS key within that specific XMSS tree.

SPHINCSLET: An Area-Efficient Accelerator for the Full SPHINCS+ Digital Signature 6 Algorithm

Algorithm 4 slh sign, Signature Generation of SLH-DSA Input: Message M, private key SK=(SK.seed, SK.prf, PK.seed, PK.root) **Output:** Signature SIG 1: ADRS = toByte(0, 32) // Initialize state 2: $opt = \mathbf{PK}.seed$ 3: $R = \mathbf{PRF}_{msg}(\mathbf{SK}.prf, opt, M)$ 4: $SIG = SIG \parallel R$ 5: $digest = \mathbf{H}_{msg}(R, \mathbf{PK}.seed, \mathbf{PK}.root, M)$ // Compute message digest and index 6: $tmp_md = first floor ((ka + 7)/8)$ bytes of digest 7: $tmp_idx_{tree} = next$ floor ((h - h/d + 7)/8) bytes of digest 8: $tmp_idx_{leaf} = next$ floor ((h/d + 7)/8) bytes of digest 9: md = first ka bits of tmp_md 10: $idx_{tree} = \text{first } h - h/d \text{ bits of } tmp_idx_{tree}$ 11: $idx_{leaf} = \text{first } h/d \text{ bits of } tmp_idx_{leaf}$ 12: $SIG_{FORS} = FORS$ sign(md, SK.seed, PK.seed, ADRS) // Compute FORS Merkle trees 13: $SIG = SIG \parallel SIG FORS$ 14: $PK_{FORS} = fors_pkFromSig(sig_fors, md, PK.seed, ADRS) //Compute Hash from$ FORS Merkle tree roots 15: **ADRS**.setType(TREE) 16: $SIG_{HT} = ht_sign(PK_{FORS}, SK.seed, PK.seed, idx_{tree}, idx_{leaf}) // WOTS^+, XMSS$

17: $SIG = SIG||SIG_{HT}$ return SIG

3.5.2 Signature Verification

Signature verification involves computing the message digest and reconstructing trees up to the hypertree root. It uses the same hash functions and similar operations for signature generation. For example, in WOTS⁺, the signature verification uses the same *chain* operation of Algorithm 2 with s = w - 1 - msg. Hence, we do not discuss details of signature verification in this chapter, and it can be obtained in [oST23].

4 Related Work

Amiet et al. [ACZ18] introduced an FPGA-based accelerator for SPHINCS-256 [BHH⁺15], which represents the earlier version of SPHINCS+ with different internal operations and hash functions. Their SPHINCS-256 architecture comprises a control unit, a BLAKE-256 hash module, a highly pipelined ChaCha12 hash module. While they presented the design with fast signing and verification, it resulted in significant resource utilization, e.g., 19K LUTs, 38K FFs, and 36 BRAMs.

Following the proposal of SPHINCS+ [BDE⁺17] for the NIST PQC standardization project, Amiet et al. [ALCZ20] presented an updated SPHINCS+ hardware implementation. They utilized a fully unrolled KECCAK pipeline, the core element of the SHAKE256 module, and targeted fast signing. Nonetheless, their implementation of SPHINCS+ utilized even greater resources, peaking at 51K LUTs, 74K FFs, and 22.5 BRAMs. They introduced a fault attack by inducing supply-voltage glitches in the SPHINCS+ FPGA implementation. To mitigate this vulnerability, they recommended duplicating the hardware. However, adopting this countermeasure would result in a doubling of the resource usage.

In order to achieve a more area-efficient SPHINCS+ core, Berthet et al. [BUG⁺21] proposed a SPHINCS+ implementation that utilizes the SHA256 hash function, which occupies small resources with 6K LUTs, 5K FFs, and 0.5 BRAM. Their design prioritized

low-area usage but resulted in slower signing and verification compared to the previous hardware implementation of [ALCZ20], lagging behind by approximately a factor of 100. As mentioned earlier in this chapter in Section 3.5, FIPS 205 mandated changes with respect to the SPHINCS+ specification, replacing SHA256 with SHA512 hash function for \mathbf{H}_{msg} , \mathbf{PRF}_{msg} , \mathbf{H} , and \mathbf{T}_{ℓ} functions. This would mean incorporating an additional SHA512 core alongside the existing SHA256 core, leading to an increase in the overall area. Therefore, the SPHINCS+-SHA256-256f-simple and SPHINCS+-SHA256-256s-simple implementations of SPHINCS+ in [BUG⁺21] are no longer compliant with the FIPS 205 specification.

Another area-efficient SPHINCS+ implementation was given by Wagner et. al in [WOS22]. The implementation is targeted at a RISC-V-based secure boot system. They focused on SHA-2-based SPHINCS+ with a 32-bit RISC-V processor, which shows signature verification faster than software. [KSS24] presented signature generation and verification of SHAKE256-based SPHINCS+ with a 32-bit RISC-V processor. They occupy 24K LUTs, 12K FFs in AMD Ultrascale+, which shows lower clock cycles than software. [Saa24] implemented SHAKE256-based and SHA-2-based SLH-DSA with a 32-bit RISC-V processor with the hardware hash modules. They accelerated design by implementing the hardware hash modules and focused on firmware control to optimize the padding format for additional improvement. The RISC-V processor communicates with the hardware hash modules occupying 14K LUTs, 9K FFs, 32 BRAMs (for an integrated design combining both SHA-2 and SHAKE256 modules), and showing lower clock cycles than previous works.

In this chapter, we introduce a standard-compliant, area-efficient SLH-DSA implementation using SHAKE256, SHA256, and SHA512. Given the highly parallelizable nature of SPHINCS+ operations, we chose to employ two low-area hash modules to construct a HASH_TILE that handles all the hashing requirements of the SLH-DSA described in Section 5.1, significantly boosting the speed of our implementation. Notably, our work also incorporates all the parameter sets and variants of SLH-DSA and implements the modifications outlined in the FIPS 205 standard.

5 SPHINCSLET - Hardware Design

Figure 1 illustrates the design overview of our SPHINCSLET implementation. Our HASH_TILE module is utilized to support the hash operations in SLH-DSA, accompanied by Finite State Machine (FSM), which is also referred as the Control Logic in Fig. 1. The FSM includes the WOTS⁺, Merkle tree, and pre/post processing sub-modules and manages the HASH_TILE to perform the SLH-DSA operations. Input and output data for the HASH_TILE is effectively managed by storing odd and even indexed nodes in two internal memories, optimizing the signature generation and verification. Based on the security level and the underlying hash function used in the SLH-DSA design, we use two different types of hardware design architectures for our SPHINCSLET design shown in Fig. 1. For all SHAKE-256 based SPHINCSLET and {128s, 128f} variants of SHA-2 based SPHINCSLET we use Fig. 1a and for {192s, 192f, 256s, 256f} variants of SHA-2 based SPHINCSLET we use Fig. 1b.

5.1 HASH_TILE

In this section, we present the details of our HASH_TILE hardware module. The hardware block design of the HASH_TILE is shown in Fig. 3. The HASH_TILE performs the hash function and pseudorandom function operations described in the [oST23, Section 4] in an efficient processor-based form. The HASH_TILE is parameterized to work with either SHAKE256, or SHA256, or SHA512 hash functions to cater the needs of SHAKE256-based SPHINCS+ and SHA-2-based SPHINCS+ designs respectively. We build our HASH_TILE

(a) SPHINCSLET module with (b) SPHINCSLET module with one two HASH_TILEs HASH_TILE

Figure 1: Overview diagram of our hardware architecture.

Figure 2: Hardware block design of SHAKE256 module.

using two hash (SHAKE256 or SHA256 or SHA512) modules, L_HASH and R_HASH as shown in the Fig. 3.

5.1.1 SHAKE256-based HASH_TILE

To construct the SHAKE256-based $\texttt{HASH_TILE},$ we design our own SHAKE256 hardware module.

SHAKE256 SHAKE256 is an extendable-output function (XOF) based on the Keccak sponge construction [BDPVA13]. SHAKE256 allows generating output of any desired length unlike fixed-length hash functions (e.g., SHA3-256, SHA3-512). It uses the Keccak-f permutation function in its construction. Keccak-f is a sponge function that operates on a state of 1600 bits. The core operation of Keccak is the Keccak-f[b] permutation, which consists of multiple rounds of transformation. The number of rounds is determined by $12+2 \times log_2(w)$ (where w is the lane size). In the SHAKE256 setting of the keccak, w = 64. Therefore, the number of rounds is 24. Each round consists of five steps: θ - diffusion, ρ - bit rotation, π - lane permutation, χ - non-linerarity, and ι - Xoring a round constant.

Fig. 2 shows the hardware design of our SHAKE256 module. In our hardware implementation of keccak-f round function, { θ , ρ , π , χ , and ι } are implemented using combinatorial logic. Our keccak-f round function implementation is a full-width round-based iterative architecture. Hence, after each round, the output is registered and fed back into the round function. Although our keccak-f round function implementation is full width, we restrict the SHAKE256 to a 64-bit input and output interface. This is because all the data fed into the SHAKE256 module is loaded from a BRAM. Hence, having a wider data width would require larger block RAM utilization.

Figure 3: Hardware block design of HASH_TILE module.

5.1.2 SHA-2-based HASH_TILE

As specified in Section 3.5, the SHA-2-based HASH_TILE is constructed either with SHA256 hash function or SHA512 hash functions depending on the security level of SLH-DSA. Both SHA256 and SHA512 belong to SHA-2 family [CKSV06].

- SHA256 generates a 256-bit (32-byte) hash value by processing 512-bit input blocks. It uses Merkle-Damgård structure with Davies-Meyer compression in its construction. It utilizes 64 rounds of bitwise operations, modular additions, and logical functions.
- The construction of SHA512 is also similar, but it operates on 1024-bit input blocks and produces a 512-bit (64-byte) hash. It uses 80 rounds and a larger word size (64-bit vs. 32-bit in SHA-256).

In security level 1, as shown in Fig. 1a, we use a single SHA256-based HASH_TILE, which is constructed using two SHA256 hash functions. In security level 3 or 5, as shown in Fig. 1b, we require two HASH_TILEs: one based on SHA256 and one based on SHA512. Each HASH_TILE is constructed using its respective two hash functions. It is noted as SHA256+SHA512-based HASH_TILE in Table 3. We utilize the SHA256 module referenced in [Str23] and the SHA512 module referenced in [Str21]. These implementations are employed in constructing our HASH_TILE due to their area efficiency, making them suitable for our low area designs. Their construction is a full-width, round-based implementation that requires external control logic to inform the modules about incoming block size, the last block, and padding. We engineer a wrapper around the SHA256 and SHA512 modules with a 64-bit interface that can manage all necessary control logic. Furthermore, it has the ability to load inputs sequentially by retrieving them from L_BRAM and R_BRAM, as illustrated in Fig. 3.

Table 2 illustrates the time and area performance of various hash modules utilized in our design. First, when we assess our SHAKE256 implementation against other efficient open-source implementations in the literature, it is evident that our design outperforms them both in terms of area and time efficiency. Second, when we compare SHA256 versus SHA512, the area is doubled due to the state size and operating word size being increased from SHA256 to SHA512.

Both SHAKE256-based HASH_TILE and SHA-2-based HASH_TILE perform a set of predefined hashing and pseudorandom function operations described in the [oST23, Section 4] in a processor-based form. Since the HASH_TILE follows a processor-like architecture, we enable all required operations through a set of opcodes. In the following list, we provide the opcodes used in both SHAKE256-based and SHA-2-based HASH_TILE design.

1. **T_L**: It represents the $\mathbf{T}_{\ell}(\mathbf{PK}.\text{seed}, \mathbf{ADRS}, M_{\ell})$ from [oST23, Section 4] in our hardware design. It is a hash operation that maps an $n + 32 + n \times k$ -byte input or an $n + 32 + n \times len$ -byte input to an *n*-byte output. The specific input size depends

SPHINCSLET: An Area-Efficient Accelerator for the Full SPHINCS+ Digital Signature 10 Algorithm

Table 2: Comparison of time and area of the hash modules targeting the AMD Artix 7 xc7a200t-3 FPGA. * Frequency is constrained to 100 MHz, maximum clock frequency is not reported.

Hash Variant		Cycles	Frequency			
	LUT	DSP	\mathbf{FF}	BRAM	-	(MHz)
SHAKE256 [our]	4,383	0	2,708	0	24	250
SHAKE256 [Saa24]	$5,\!443$	0	$2,\!445$	0	24	100^{*}
SHAKE256 $[DXN^+23]$	4,797	0	$1,\!845$	0	74	166
SHA256 [Str23]	1,758	0	$1,\!052$	0	66	113
SHA512 [Str21]	$3,\!175$	0	$2,\!101$	0	82	110

on the chosen operation, which includes WOTS⁺ public key compression and FORS root compression.

- 2. **PRF**: It represents the **PRF**(**PK**.seed, **SK**.seed, **ADRS**) from [oST23, Section 4] in our hardware design. It is a pseudorandom function that generates the secret values in WOTS⁺ and FORS private keys. It take 2n + 32-byte input and generates *n*-bytes of pseudorandomness.
- 3. H: It represents the H(PK.seed, ADRS, M_2) from [oST23, Section 4] in our hardware design. It is a special case of T_{ℓ} , which takes a 3n + 32-byte input and generates hash of *n*-bytes. This function is used in Merkle tree generation in both FORS and XMSS.
- 4. **H_MSG**: It represents the $\mathbf{H}_{msg}(R, \mathbf{PK}.\text{seed}, \mathbf{PK}.\text{root}, M)$ from [oST23, Section 4] in our hardware design. It is used for computing the message digest of the message to be signed. It takes (3n + Message Size) bytes as input and generates $\lfloor (k \times \log(t) + 7)/8 \rfloor + \lfloor (h h/d + 7)/8 \rfloor + \lfloor (h/d + 7)/8 \rfloor$ -byte output.
- 5. F: It represents the $\mathbf{F}(\mathbf{PK}.\text{seed}, \mathbf{ADRS}, M_1)$ from [oST23, Section 4] in our hardware design. It is a hash function that takes an 2n + 32-byte input and produces an *n*-byte output. It is used in iterating over WOTS⁺ chains and generating the FORS leaves.
- 6. **PRF_MSG**: It represents the **PRF**_{msg}(**SK**.prf, OptRand, M) from [oST23, Section 4] in our hardware design. A pseudorandom function that generates the randomizer for the randomized hashing of the message to be signed. It takes (n + 32 + Message Size)-byte input and generates n-bytes of randomness.
- 7. **F_WOTS_PLUS_h**: This is a special case which we design in our HASH_TILE using the **F** case. While computing the WOTS⁺ public key and WOTS⁺ signature, the **F** operation needs to be iterated. To minimize the input write and output read cycles, required iteration number is taken as input and the final result is computed by iterating **F** for the necessary number of times. For each iteration, the **ADRS** value from the **F** operation needs to be updated, and this is handled internally by the control logic shown in Fig. 3.
- 8. **H_TREE**: This is a special extension of **H** which we design in our HASH_TILE, which computes one level of a Merkle tree. It computes the hash of two child nodes using the L_HASH and R_HASH in parallel, followed by hash for the parent node using the L_HASH and returns the hash for the parent node as a result. We compute the tree for two reasons: 1. to minimize the cycles. 2. to reduce the complexity of the main control logic of our design.

We note from the aforementioned list of opcodes, all operations except H_TREE can be performed in sets of two because we have L_HASH and R_HASH. We also note that depending on the selected opcode, the HASH_TILE operates in two modes, namely, streaming mode and regular mode. The regular mode is used for the opcode {T_L, PRF, H, F, F_WOTS_PLUS_h, H_TREE} where the input and output sizes are fixed. In the regular mode, the data inputs and outputs move through the BRAMs. The opcode {H_MSG, PRF_MSG} uses the streaming mode because one of the inputs required in these modes is the message input. The message is not of fixed length; hence, the HASH_TILE allows a variable-length message to be streamed through the FIFO. The output still moves through the BRAMs. The variable length messages add complexity of maintaining the order of all required inputs in opcode {H_MSG, PRF_MSG}, and this is managed by the Pre/Post processing block, which is part of the Control logic (shown in Fig. 1).

The reason we choose to store and retrieve the data through the BRAMs is that in most of the modes presented in Table 3, the output hash is fed as input in the next iteration of the hash computation. Consequently, to save the data load out and load in cycles, we write the hash to the appropriate memory location. For a given parameter set (shown in Table 1), and specific HASH_TILE opcode the number of blocks read from or written to the memory and the address locations remain constant. Therefore the design remains constant-time, avoiding any chance of leakages due to non-constant time behavior. The HASH_TILE also has optional output ports that are coming out of the L_HASH and R_HASH directly without passing through BRAMs. These ports are not shown in the Fig. 3 because we do not use them in our SPHINCSLET design described in Section 5.

Our HASH_TILE module has modular structure, which allows us to easily swap between SHAKE256, SHA256, and SHA512 hash functions. We highlight that this parameterizability facilitates us to have a single same top-level control logic (described in Section 5.2) for different parameter sets and different underlying hash functions. As discussed in Section 5, the HASH_TILE is integral to building a purely hardware-based SPHINCSLET module. Its BRAM-based interface enables the HASH_TILE to function effectively as a co-processor as well.

5.2 FSM (Control Logic) Design

Algorithm 4 shows the algorithm for SLH-DSA signature generation, its operational flow could be visualized with Fig. 4, and our hardware block design in shown in Fig. 1. The SLH-DSA signing construction mainly consists of three main schemes: FORS, XMSS, and WOTS⁺ (described in Section 3). In our hardware design, the flow of the operations is handled by the control logic to effectively handle our HASH_TILE design. Firstly, the Pre/Post Processing FSM loads the inputs message (M), public key seed (**PF**.seed) and PRF key (**SK**.prf) in to the HASH_TILE and initiates the **PRF** mode from the HASH_TILE to generate the pseudorandom bits (R). A copy of the R remains in the internal memory inside the HASH_TILE. Along with that, the Pre/Post Processing FSM loads **PF**.seed, and top root node (**PF**.root) in the HASH_TILE and **H_MSG** mode is set to generate the message digest.

Following that, the FORS FSM is initiated. The FORS FSM takes the inputs message digest, secret seed (**SK**.*seed*), **PF**.*seed* and context information in the form of an address (**ADRS**) and generates a FORS public key using multiple FORS trees as described in Section 3.4. The root node of the FORS tree (which is the FORS public key) is then loaded into the WOTS⁺ scheme. The WOTS⁺ scheme uses a **SK**.*seed*, **PK**.*seed*, and **ADRS** to generate a secret key ($sk_0, sk_1, ..., sk_{len-1}$). Then, the WOTS⁺ secret key undergoes '(w - 1) *iterations*' of **F** mode of hashing to generate a WOTS⁺ public key (as shown in Fig. 5). In WOTS⁺ computation, we generate the leaf nodes of XMSS, as shown in Fig. 5, we employ a chain-parallel approach using **HASH_TILE**. The FSM design

Figure 4: Dataflow diagram of SLH-DSA.

in [ALCZ20] focused on chain operation in WOTS⁺ uses one-by-one approach to achieve the high throughput with one big pipelined hash module, while our FSM design uses the HASH_TILE, which contains two small hash modules, and utilizes the parallelism of the WOTS⁺ chain. Once all operations for each chain are complete, we obtain a public key consisting of *len* blocks, each of *n* bytes (given in Table 1), which is compressed to form a single leaf node using opcode $\mathbf{T}_{\mathbf{L}}$. In our hardware design, all the WOTS⁺ related operations are handled by the WOTS⁺ FSM (shown in Fig. 1). The WOTS⁺ public key is then loaded into the XMSS scheme. Similar to the FORS, the XMSS scheme also uses Merkle trees to generate the signature. However, the parameter sizes for the Merkle trees in FORS and XMSS differ. The WOTS⁺ and XMSS schemes are repeated iteratively for *d* layers (given in Table 1) for signature generation or signature verification computations.

The computational flow of signature generation and verification of SLH-DSA is very similar as specified in [oST23]. Hence, we design our SPHINCSLET hardware design control logic (shown in Fig. 1) in a way that it can handle both operations. The key differences between the signature generation and signature verification are as follows: 1) In signature generation, for the XMSS and FORS computation, we need to compute all the nodes of the Merkle tree to generate the root node. Whereas in signature verification, we only need to compute one hash per layer in a Merkle tree, based on the provided neighboring node information. 2) In the signature generation process, we perform the WOTS⁺ signing operation with m or w iterations of hash computations at each chain operation using **F_WOTS_PLUS_h** (described in Section 5.1). Whereas in signature verification, WOTS⁺ signature is verified by iterating over the chain operation for only (w - m - 1) times, which is also handled by the **F_WOTS_PLUS_h**.

Merkle Trees As described in Section 3.2 and Section 3.4, FORS and XMSS schemes include computing Merkle trees, which have similar dataflow. Notable differences between that schemes include the method of leaf node generation and the size of the Merkle trees. Nonetheless, the underlying operation remains the same (i.e., hash computation on each node) Therefore, in our control logic, we designed a parameterizable Merkle tree FSM that takes the tree height and the number of leaf nodes as inputs, making our Merkle tree FSM adaptable for both FORS and XMSS operations. Additionally, this also contributes to the reduction in the area utilization. To support the leaf node generation for XMSS and

Figure 5: Dataflow diagram of WOTS⁺ PK generation. $(sk_0, sk_1..., sk_{len-1})$ and $(pk_0, pk_1..., pk_{len-1})$ refers to WOTS⁺ secret and public keys respectively.

Figure 6: Dataflow diagram of Merkle tree, circled numbers represent order of the data being processed.

FORS, our WOTS⁺ processor uses different hash types described in the Section 5.1 (**PRF**, **F_WOTS_PLUS_h**, and **T_L** for XMSS and **PRF** and **F** for FORS computation). As mentioned at the beginning of this Section 5.2, the Merkle tree is parameterized to work for both XMSS and FORS operations since they share the same structure. Fig. 6 shows an example dataflow of the Merkle tree generation for XMSS. The dataflow for FORS (shown in Fig. 4) is the same except the inputs of the leaf nodes are part of FORS secret keys, instead of WOTS+ public key.

In the Merkle tree operations, two child nodes are taken as an input for one hash operation. As HASH_TILE can operate two hashes in parallel, a total of four child nodes are received as input. The child nodes are stacked to the internal BRAM by checking the index of the parent node's **ADRS**. The result is stored back in the internal BRAM to prepare for the subsequent operations i.e., the hash computation of the next node in the Merkle tree. This minimizes input loading and output retrieval cycles.

To efficiently utilize the $HASH_TILE$ design along with internal BRAM, Merkle tree computations are performed in units of four nodes. The process begins with the computation of leaf nodes using WOTS+ public key generation (illustrated in Fig. 5), starting from the leftmost node. Once four leaf nodes are computed, an **H** hash operation (denoted as operation 1 in Fig. 6) is performed to generate two parent nodes at the upper level of the Merkle tree. Repeating this process once more results in four nodes at the upper level, which are then processed using another H hash operation (operation 3 in Fig. 6). If additional leaf nodes remain, the computation returns to the lower level to process the next set of four nodes. In cases where no leaf nodes remain (as seen in Fig. 6), a final H hash operation (operation 4) is performed at the upper level. This approach enables efficient BRAM utilization by limiting storage to only four nodes per level. The sequence of computations is outlined in Fig. 6, demonstrating an optimized traversal strategy. Additionally, this method ensures that both the L_SHAKE and R_SHAKE components of the HASH_TILE (illustrated in Fig. 3) are consistently utilized in parallel, maximizing SPHINCSLET: An Area-Efficient Accelerator for the Full SPHINCS+ Digital Signature 14 Algorithm

Table 3: Area utilization of the SHAKE-based and SHA-2-based HASH_TILEs and time taken for performing each opcode operation by the HASH_TILE targeting the AMD Artix 7 xc7a200t-3 FPGA. Please note that except for opcode H_TREE, for all other opcodes the time shown is to perform a set of two operations.

computational efficiency.

6 Evaluation

In this section, we evaluate different hardware modules described in Section 5 and provide a detailed comparison with the existing work. For the evaluation and comparison with the related work, we use the following metrics: for the area, we use look-up-tables (LUTs), Flipflops (FF), and Block RAM (BRAM), and for timing, we use clock cycles, maximum clock frequency (F_{max}), and time. For our work, the area results are extracted from post-implementation area reports of the AMD Vivado synthesis tool, and for timing, the clock cycles are computed using the simulations, and F_{max} is computed from post-implementation timing reports. We verify the functional correctness of our implementation with the reference implementation [BDE⁺].

6.1 Evaluation of the HASH_TILE

Table 3 shows the performance results of our HASH_TILE module considering the parameter sizes for SLH-DSA-128s parameter set (values given in Table 1). The area results shown for SHA256+SHA512 based HASH_TILE sum of two individual SHA256 and SHA512 based HASH_TILE. Since this configuration is only used in {192s, 192f, 256s, 256f}, we present an example considering the SHA-2 based SLH-DSA 192s configuration.

6.2 Evaluation of FSM Design

We note that, as shown in Table 4, FSM hardware design remains similar for both SHAKE256-based design and SHA-2-based design in various parameter sets of SLH-DSA. The only change lies in the input format of the **ADRS**. In SHAKE256-based design, the **ADRS** size is 32 bytes, which includes layer address, type, padding, and index. As shown in Table 4, the utilization of internal BRAMs remains consistent across all parameter sets

Parameter Set		Area									
	LUT	\mathbf{FF}	BRAM	(MHz)

256f	1,866	3,267	4	100							
256s	1,923	$3,\!290$	4	100							

Table 4: Area utilization of the FSMs and internal memory in the SHAKE-based and SHA-2-based designs targeting the AMD Artix 7 xc7a200t-3 FPGA.

of SLH-DSA. This is because the maximum BRAM usage is dictated by the height of the Merkle tree in FORS, which is the tallest Merkle tree in SLH-DSA, and is given by $\log t$ (refer to Table 1). Consequently, even for the parameter set with the highest Merkle tree, the total BRAM utilization does not exceed 4 BRAM units. Additionally, the *s* variant of the parameter sets features a taller Merkle tree compared to the *f* variant, leading to differences in structural depth while maintaining the same BRAM constraints.

6.3 Evaluation of SPHINCSLET

Our SHAKE256-based and SHA-2-based SPHINCSLET hardware design results are shown in Table 5 and Table 6 respectively. These results are post-implementation results targeted to AMD Artix 7 (xc7a200t-3) FPGA and are generated using AMD Vivado 2024.2. Additionally, for SHA-2-based SPHINCSLET design, we also tabulate results targeting AMD Ultrascale+ (xczu3eg-2) FPGA in Table 6 for fair comparison with the related work [BUG⁺21].

6.3.1 Performance Comparison with Full Hardware Design

In Table 5, we present the results for all possible variants of our SHAKE256-based SPHINCSLET designs, comparing them to the most recent and relevant full hardware implementation of the SPHINCS+ signature scheme at various security levels [ALCZ20], which also utilizes SHAKE256 as the hash function in its construction. While the design in [ALCZ20] takes less time to compute both signature generation (t_{sign}) and signature verification (t_{verify}) than our hardware design, we note that all of our designs take significantly less area. We acknowledge that the SHAKE256 design presented in [ALCZ20] is a full-width implementation that is heavily pipelined, providing an inherent advantage with several independent hash computations in SPHINCS+. However, this advantage costs 47K-51K LUTs and 72K-74K flip-flops, making the design unsuitable for lightweight applications. Hence, to achieve a lower area design in our approach, we avoid pipelining in

Table 5: Comparison of our SHAKE256-based SPHINCSLET hardware implementation with other SPHINCS+ hardware implementations that use SHAKE256 as the underlying hash function.

Par. = Parameter Set, HW = Hardware, CC = Clock Cycles, t = Time

our SHAKE256 (rather we opt for round-based iterative architecture). Our SPHINCSLET hardware design utilizes under 10.8K LUTs, 7.7K flip-flops, and 8 BRAMs, which on average results in $4.7 \times$ lower LUT consumption, $9.7 \times$ lower flip-flops, and lesser BRAMs utilized when compared to [ALCZ20].

Additionally, in Table 6, we tabulate the results for all potential variants of our SHA-2based SPHINCSLET designs compared to the most recent non-standard compliant SHA-2based SPHINCS+ across various security levels [BUG⁺21]. As described in Section 3.5, the impact of standard compliance is more pronounced in SHA-2-based SPHINCS designs because the standard suggests utilizing both SHA256 and SHA512 in parameter sets {192f, 192s, 256f, and 256s}, while for parameter sets {128f and 128s}, only SHA256 is employed. As noted in Section 5.1, we implement the design from Fig. 1a for single HASH_TILE configurations such as parameter sets {128f and 128s}. We also implement the design from Fig. 1b for dual HASH_TILEs, applicable to parameter sets {192f, 192s, 256f, and 256s}. In addition to presenting synthesized results for AMD Artix 7 (xc7a200t), we include results

Table 6: Performance comparison of SLH-DSA and SPHINCS+ hardware implementations that use hash functions other than SHAKE256. (Note that all designs have 0 DSP.)

CC = Clock Cycles, t = Time

for our design targeting AMD Ultrascale+ (xczu3eg) FPGA to ensure a fair comparison with the design introduced in $[BUG^+21]$. From Table 6, we observe that our SHA-2-based SPHINCSLET design is $2 \times -3 \times$ faster compared to the existing non-standard compliant SPHINCS+ design in $[BUG^+21]$, with a smaller area for parameter sets {128f and 128s}. In terms of memory resources, the design in $[BUG^+21]$ exhibits a compact size of the BRAM, which transfers results to the host after each operation. This transfer back to the host incurs significant time overhead. Conversely, our design utilizes more BRAM than [BUG⁺21], storing all data on the FPGA and eliminating the time overhead associated with data transfers. For parameter sets {192f, 192s, 256f, and 256s}, the area increase is inherent due to the inclusion of both SHA256 and SHA512 HASH_TILE shown in Fig. 1b.

6.3.2 Performance Comparison with HW-SW Codesign

In Table 5, we compare our design with two RISC-V-based designs that use SHAKE as a hash function targeting the AMD Artix 7 and Ultrascale+. Out of these two RISC-V-based works, our hardware design significantly outperforms [KSS24] in both area and

timing aspects. [Saa24] is a more recent and optimized design that is fully standard compliant, similar to ours; therefore, we evaluate our work against [Saa24]. The Keccak round implementation from [Saa24] also presents a full-width implementation (taking one round per clock cycle), which is similar to our SHAKE256 module described in Section 5.1. We note that our overall SLH-DSA hardware implementation has a slightly larger area footprint than the implementation presented in [Saa24], this is due to usage of two SHAKE256 modules inside the HASH_TILE. However, our BRAM utilization is significantly smaller. The design proposed in [Saa24] relies on BRAM to store all intermediate data and program files due to its use of a RISC-V processor. In contrast, our design requires significantly less BRAM storage by minimizing the amount of intermediate data retained during computations. For instance, in Merkle tree operations, only the data for four nodes per level is necessary for computation. As a result, we store only these four leaf nodes, reducing overall intermediate data storage and, consequently, lowering BRAM utilization. In terms of timing comparison, our design is $2.5 \times$ to $5.3 \times$ faster for signature generation and $2.3 \times$ to $3.4 \times$ faster for signature verification across various parameter sets compared to [Saa24]. One reason for this speed-up is that our design utilizes two SHAKE256 modules in parallel, maximizing all possible parallel hash computations. Additionally, as stated in [Saa24], the RISC-V module connects to the Keccak round accelerator via a 32-bit interconnect. It also incurs some penalty cycles from the RISC-V core for instruction fetch, both of which contribute to the overall timing.

In Table 6, we compare our design against the SHA2-based SPHINCS+ designs. Even in this case, our design uses more area footprint than that reported in [Saa24, WOS22]. This is due to the use of two hash modules within the HASH_TILE module. In case of high security level parameter sets i.e., {192s, 192f, 256s, 256f}, we use two HASH_TILE one consisting two SHA256 modules and the other consisting of two SHA512 modules. Our BRAM utilization is lower compared to [Saa24], and [WOS22] did not report the number of BRAM used, as they employ the register interface to communicate between RISC-V and the hash hardware module. Our SHA-2 based SPHINCSLET design significantly outperforms all other existing modules in terms of both signature generation and signature verification times, making it the fastest SHA-2 based SPHINCS+ design.

7 Conclusion

In this work, we introduced SPHINCSLET, a fully standard-compliant and areaefficient hardware implementation of the SLH-DSA (formerly SPHINCS+) post-quantum digital signature scheme. Our design strikes an optimal balance between hardware area and performance, addressing the limitations of existing implementations that either sacrifice area efficiency for speed or rely on coprocessor-based architectures with significant performance overhead. Through our SHAKE256-based implementation, we achieved a $4.7 \times$ reduction in area compared to high-speed designs while maintaining a $2.5 \times$ to $5 \times$ faster signing time than the most efficient coprocessor-based alternatives. Additionally, our SHA-2based implementation demonstrated a $2 \times$ to $4 \times$ speedup in signature generation while maintaining a compact area footprint of 6K to 15K LUTs, making it the fastest SHA-2based SLH-DSA hardware implementation to date. By requiring fewer than 10.8K LUTs on an AMD Artix-7 FPGA for a SHAKE256-based SPHINCS+, our SPHINCSLET design proves to be a highly practical solution for resource-constrained devices, ensuring an efficient transition to post-quantum cryptography.
